It should be noted that a one-step dispersion may not be able to fully separate individual NPs. A complete disaggregation of NPs requires that the interaction forces such as van der Waals attractions and organo-mineral interactions are overcome. Therefore, the application of chemical extractants always helps to disperse NPs more extensively. For example, alkaline conditions enhance SOM solubilization or desorption and may favor the disaggregation process of organo-mineral hetero-aggregates. Thus, a pretreatment of soil particles using NaOH, Na₂CO₃, or Na₄P₂O₇ is always of value. In addition, chemical reagents such as Na₂C₂O₄, EDTA, and Na₄P₂O₇, could be applied to complex multivalent cations released from clays. Such complexation prevents specific adsorption of multivalent cations onto particles, which is also beneficial for dispersion of the aggregates. Phosphate-based extractants are also shown to adsorb specifically on to colloids, modify their surface charge, and facilitate disaggregation processes.

After an effective dispersion of the particles, NPs may be obtained through particle separation. At present, the technology for the separation of NPs includes membrane separation (such as filtration, microfiltration, and ultrafiltration dialysis), size exclusion chromatography (SEC), hydrodynamic chromatography (HDC), and field flow fractionation (FFF). The dispersion and separation will eventually ensure a quantitative or qualitative analysis of NPs using various 'back-end' detection equipment, such as the UV-Visible spectrum (UV-Vis), inductively coupled plasma mass spectrometry (ICP-MS), multiangle laser light scattering (MALS) and dynamic light scattering (DLS). Size distribution of various types of NPs and some common analytical techniques are summarized in Fig. 1 (Klaine et al., 2008).

Techniques in nanoparticle characterizations

The particle size of NPs is one of the most important indicators to characterize their physical and chemical properties. Various methods and instruments are applied for particle-size analysis of NPs, but each technique has its own advantages and disadvantages. Currently, DLS is the most widely used instrument to determine the particle-size distribution of NPs in the aqueous phase. This technique is based on Brownian motion, and measures particles down to 2 nm. However, because the intensity of scattered light is proportional to the sixth power of the particle diameter, the analysis is heavily weighted towards larger particles. Considering the highly heterogeneous size distributions in soil, the detection of small particles may be greatly shielded by the larger particles. A preliminary separation of soil particles into different particles-size ranges may greatly enhance the reliability of DLS determination.

Nano particle tracking analysis (NTA) is also a light scattering technique for analyzing the size distribution of NPs with high resolution, which tracks the Brownian motion of NPs in suspension in real time. The particle-size distribution and concentrations are obtained using Stokes-Einstein equation. During NTA measurement, individual particles are identified and tracked, and the distance travelled by the particle in each time period is related to their hydrodynamic diameter. Thus, the NTA technique is a combination of DLS and image analysis. Because NTA tracks individual particles, it is not limited by polydisperse samples as for DLS. This technique also shows high sensitivity to particle numbers and size distributions, and requires less time than microscopic techniques. The NTA method has been successfully used in detecting NPs in environmental samples, such as fullerenes and TiO₂ NPs in river water, as well as municipal solid waste leachate. A drawback of NTA is its detection limitations, and reliable data cannot be obtained for particles below 20 nm. In addition, we cannot directly observe the morphology, structure and chemical composition of NPs by NTA, and thus a combination of image analysis is always advantageous.

Microscopy-based image analysis, such as transmission electron microscopy (TEM), scanning electron microscopy (SEM), scanning transmission electron microscopy (STEM), and atomic force microscopy (AFM), have been successfully used in the characterization of NP morphology, dispersion and size distribution. These microscopic techniques break through the limitation of 0.2 µm for traditional optical microscopes and can observe particles at a much higher resolution. For example, during TEM analysis, a short-wavelength electron beam penetrates the sample and then magnifies the image. The resolution of TEM is related to the electron beam acceleration voltage. Considering the 80–300 kV electron beam acceleration voltage applied in TEM measurement, the resolution could reach 0.1–0.2 nm. High-end TEM can even achieve atomic resolution.

Scanning electron microscopy is a technique that combines TEM and the optical microscope. It uses a very narrow focused high-energy electron beam to scan the sample. The instrument collects optical signals excited during the interaction between the beam and the substance, and magnifies the information and images to characterize the microscopic morphology of the substance.

Fig. 1 Size distribution of various types of particles and their characterization techniques (FFF: field-flow fractionation; FCS: fluorescence correlation spectroscopy; LIBD: laser induced breakdown detection) (Klaine et al., 2008). From Klaine SJ, Alvarez PJ, Batley GE, Fernandes TF, Handy RD, Lyon DY, Mahendra S, McLaughlin MJ and Lead JR (2008) Nanomaterials in the environment: behavior, fate, bioavailability, and effects. *Environmental Toxicology and Chemistry* 27(9): 1825–1851. Reprinted with permission from John Wiley & Sons.

The scanning electron microscope's resolution can reach 1 nm, and the magnification can reach 300,000 times or more. Atomic force microscopy is also a powerful technique to study the surface structure of solid materials including insulators. It can detect the very weak interatomic interaction between the sample surface and a micro force sensor. When scanning the sample, the sensor detects the deformation or motion changes of the microcantilever. The surface morphology, roughness, and structural information are obtained with nanoscale resolution based on the information obtained on force distribution.

Techniques for distinguishing natural and engineered nanoparticles

Engineered nanoparticles (ENPs) possess some technically intensified properties not involved in biotic evolution. Therefore, their ecological risks are much stronger than NNPs. It is thus essential to develop analytical approaches to distinguish NNPs and ENPs in complex environmental matrices, especially in soils. The challenges in identifying ENPs in complex environmental matrices include: (1) the low concentration of ENPs (several order of magnitude lower) relative to NNPs; (2) similarity in the chemical compositions between ENPs and NNPs, and (3) the tendency of ENPs and NNPs to hetero-aggregate in the natural environment. A general process of separation and identification of NNPs and ENPs from soil is shown in Fig. 2.

Fig. 2 Flow diagram of separation and identification of natural and engineered NPs from soil.

In soils, the majority of inorganic NNPs form during the weathering of parent materials. Thus, natural nanomaterials are likely to have similar elemental compositions to those of the rocks from which they form. For instance, natural TiO_2 minerals such as rutile and ilmenite are the main carriers (>90–95% of the whole-rock content) for titanium (Ti), Niobium (Nb), antimony (Sb), and tantalum (Ta), and important carriers (5–45% of the whole-rock content) for chromium (Cr), vanadium (V), tin (Sn), and molybdenum (Mo). Therefore, microelement analysis of the co-occurrence of elements is also one of the effective methods to distinguish ENPs and NNPs.

The elemental compositions of NPs may be easily quantified through spectral analysis, such as atomic absorption spectroscopy (AAS), plasma inductively coupled plasma emission spectroscopy (ICP-AES) and X-ray fluorescence spectroscopy (XRF), or mass spectrometry, such as ICP-MS and secondary ion mass spectrometry (SIMS), or energy spectrum analysis represented by X-ray photoelectron spectroscopy (XPS). The ICP-MS is one of the most widely used techniques to quantify inorganic NPs, because of its low concentration detection limits (down to ng L^{-1}). Inductively coupled plasma optical emission spectrometer (ICP-OES) provides detection limits in the $\mu\text{g L}^{-1}$ range, and AAS offers a detection limit in between this and ICP-MS. If the particles are individually separated, the following quantification techniques will be much more powerful for distinguishing between NNPs and ENPs. For example, asymmetric flow field-flow fractionation (AFFF) separates NPs according to their diffusion, which can be converted to equivalent hydrodynamic diameter according to the Stokes-Einstein equation. When combined with ICP-MS, this technique enables size fractionation and online analysis of the elemental composition of NPs. A critical step in the AFFF analyses of soil NPs is their dispersion into a colloidally stable suspension. Single particle ICP-MS (Sp-ICP-MS) is another continuous separation technique assisted by on-line ICP-MS. This joint system provides important information about the number, concentration and element mass content of NPs. The detection limits for Sp-ICP-MS are within the range of 1000 particles mL^{-1} for the number concentration, and 10–20 nm for the size of the mono-element NPs or >100 nm for oxides. The main goal of these techniques is to determine the total element concentration in the sample, but not physicochemical form (dissolved or particulate) or the size, charge or aggregation state.

The previously discussed electron microscopies are based on the analysis of separated particles. The size, shape, aggregation status and surface coating of particles can be directly observed. If other valid techniques could be combined with the microscopic methods, the NPs could also be effectively quantified. For example, the elemental composition (energy dispersive spectrometer, EDS) and phase structure (selected area electron diffraction, SAED) analysis of the particles are valuable complementary measures to the microscopies. Electron microscopy is also an effective method to distinguish ENPs. The HR-TEM with EDS and SEAD functions have been successfully applied to observe the polycrystalline structure of ZnS NPs (Kim et al., 2010). Considering the polycrystalline form of abiogenic ZnS NPs and the single crystals of biogenic ZnS NPs, the mechanisms of formation by abiotic processes could be extensively discussed.

The fate of nanoparticles in soil

Nanoparticles may undergo a series of morphological transformations through biological and abiotic processes in soil, including dissolution, transport, aggregation, dispersion, and aging (Tourinho et al., 2012). These environmental processes will ultimately change the persistence, bioavailability/bio-absorption, reactivity, and toxicity of NPs. Therefore, understanding the behavior of NPs is fundamental for recognizing their environmental risks and applications (Nowack and Bucheli, 2007). It should be noted that processes associated with NPs in water are different from those in soil where NPs may easily contact and interact with other soil components; this will be discussed in detail below. Thus, the dispersion and aggregation of NPs will not be included in this section, and readers are recommended to refer to previous review papers (for example, Zhang et al., 2020).

The dissolution of nanoparticles in the soil system

The dissolution of NPs refers to the process in which chemical components separate from the solid particles and diffuse into the liquid medium to form a homogeneous mixture. The extent of dissolution (solubility) is determined by the solubility of the chemical constituent in a given environment, and the rate of dissolution (kinetics) is determined by the concentration gradient and contact area between the bulk solution phase and particle surface. The kinetics of dissolution for solid NPs can be described by the Noyes-Whitney equation. The concentration of solute components can be calculated from the solubility of the solute in bulk solution, dissolution time, and the dissolution rate constant. The rate constant is positively related to the diffusion coefficient of solute components and the surface area of NPs (Borm et al., 2006), but inversely proportional to the thickness of the diffusion layer.

The effect of pH conditions on the dissolution of NPs is important. The NPs could react with H^+ (hydrogen ion) and promote the release of metal ions, or react with OH^- (hydroxyl group) to generate metallic hydroxyl complexes. Increasing the concentration of H^+ or OH^- in the soil medium will accelerate the dissolution. In general, environmental pH alters the dissolution equilibrium of a complexing agent, the protonation or hydroxylation of the ionic groups released by NP dissolution, and the NP interfacial free energy. Thus, the pH value plays a complex role in NP dissolution, depending on the structures of the complexing agents and the NPs together with their interaction strengths with the solvent.

Dissolved organic matter (DOM) is ubiquitous in the soil solution and may be actively involved in the dissolution of NPs. They contain a large number of oxygen-containing functional groups such as phenolic hydroxyl groups and carboxyl groups, which complex with the released metal cations. According to the Le Chatelier principle of chemical reaction equilibrium, coordination complexation leads to a decrease of the free ion concentration, which consequently increases the concentration gradient and promotes the dissolution of NPs. At the same time, H^+ will be released when DOM is complexed with metal cations, which is also beneficial to the dissolution of NPs as discussed above.

It should be noted that some researchers also found that DOM can inhibit the dissolution of NPs. After the adsorption of DOM on to the NPs, the thickness of the surface diffusion layer of the entire particle increases accordingly, and the dissolution of NPs is inhibited. The apparent effect of DOM on dissolution of NPs therefore depends on the balance between these two opposite effects. However, it is easy to imagine that the interactions between DOM and NPs will depend strongly on the DOM-NP pairs, and it may not be practical to propose a universal parameter, or a DOM concentration range to predict the apparent dissolution of NPs. If we have to choose between the accuracy and feasibility, a direct measurement of the exposed surface area of NPs after DOM sorption may be a useful value to predict NP dissolution.

The dissolution of NPs is also related to biological processes. For example, microorganisms and plants in soil systems may excrete different types of chemicals with abundant H^+ (such as organic acids) or strong redox potential. Furthermore, the chemicals released during the decomposition of microorganisms and plants may also interact with NPs. All the soil organism-related chemicals may act in a similar way to DOM in controlling NP dissolution.

The dissolution of NPs may be controlled by the above properties and processes, individually or simultaneously. A comprehensive model to predict NP dissolution considering the contribution of and even the balance among different processes will be valuable for the management of NPs. A modeling concept of the combination of processes and metal speciation, similar to MINTEQA (Bonito et al., 2018), may be of value for the mathematical simulation of NP dissolution.

The transport of nanoparticles in the soil system

The interaction between NPs and soil particles is the key to determine their transport, which can be described by colloidal filtration theory and is recognized as three main interactions, namely interception, sedimentation, and diffusion (Abbas et al., 2020). Interception occurs mainly in the direction of water flow when the distance between their transport trajectory and the surface of soil particles is shorter than the radius of the NPs. The NPs are attached to the surface of soil particles which settle under gravity. Diffusion is by Brownian motion during which NPs interact with soil particles.

The Derjaguin-Landau-Verwey-Overbeek (DLVO) theory is the most widely used theory to describe the NP-soil interaction. The classic DLVO theory describes Van der Waals force and the electric double layer force between NPs and soil particles. Their interaction energy can be calculated semi-quantitatively. When the distance between NPs and soil particles is smaller than 5 nm, short-range DLVO forces should be considered, including the hydration force, hydrophobic force, and steric resistance force. However, mismatches are usually observed between the theoretical predictions and experimental measurements. For example, DLVO theory considers the particle size and surface charge well, but not the shape. Namely, this model assumes that the particles are spheres, which is not true in most circumstances. The aggregates of spherical NPs may be relatively more compact and generally spherical compared to other shapes, which again is not considered in DLVO theory. The extended DLVO model considers particles of different morphologies well, which is a great step forward in describing the environmental behavior of NPs.

The mobility of ENPs can be quite different in different porous media. For example, nC_{60} was retained by sand (77%) more effectively than by glass beads (8–49%) (Wang et al., 2008), probably because of their different surface charges and roughness. Previous studies have demonstrated that the heavy metal compounds (mainly metal oxyhydroxides) can strongly retain ENPs in their porous structure (Tian et al., 2010). Under saturated conditions when soil pores are filled with water, the subsurface environment is a two-phase space where solid-water interfacial interactions and pore straining mainly control the transport processes of ENPs.

It is interesting to note that NP transport may also change soil properties such as electron conductivity and the microbial community, which are essential to the soil system. In addition, the sorption of various chemicals on NPs is generally over two orders of magnitude greater than on the soil particles (Fang et al., 2009). The transport and subsequent release of these chemicals by NPs in the soil column may result in the depletion of these chemicals in the current soil layer, but may be enriched in the soil layers below. The effect of this co-transport therefore depends on the type of the chemicals. For example, if the transported chemicals are nutrients, the deeper soil layers will in essence be fertilized. However, if a pollutant was carried by the NPs, the risks may be spread more widely.

The aging of nanoparticles in the soil system

The NPs in soil will inevitably be involved in geochemical processes, leading to changes in their physiochemical properties. This process is called the ‘aging’ of NPs, which includes physical, chemical, and biological processes (Mia et al., 2017). Apparently, NP aging may include the previously discussed individual processes, such as dissolution, transport, and their interactions with environmental matrices.

The aging process requires us to consider NPs as dynamic particles with continuously varying physicochemical properties. Since the individual processes will be discussed separately in the chapter, we use this section to emphasize three viewpoints. (1) The change of NP properties may not be monotonic. For example, although dissolution and decreased particle size are involved in the initial process of Au (gold) NP aging, a subsequent increase in particle size may occur because of Ostwald ripening (Gubicza et al., 2013). This ripening process occurs because large particles are favored more strongly than the small particles. This is different from aggregation and demands a special theoretical concept in mathematical modeling. (2) The shape of NPs may be changed following matrix or crystalline reformation. For a macroparticle, the edges may be gradually worn and the particle becomes spherical. However, for NPs, the spherical particles may be changed to bipyramid, decahedron, deca-tetrahedron, triangular plate, and rod shapes after aging (Gubicza et al., 2013). Proper consideration and description of the change in shape of NPs will be essential for modeling NP fate during their aging. (3) The surface redox reaction may accelerate or inhibit the following reaction of NPs. A typical example is nZVI (nonzerovalent iron) NPs. Some of the zerovalent iron atoms on the surface may be oxidized to Fe (III), which greatly weakened or enhanced the reactivity of nZVI NPs (Reinsch et al., 2010). Thus, the environmental roles and toxicity of nZVI NPs both decreased after aging.

According to the above discussion, it is thus easy to understand that the aging of NPs warrants a complete re-evaluation of the behavior and risks of NPs after they are released into the environment. The NPs should be considered extremely dynamic anthropogenic particles, especially when considering their interactions with soil components, as discussed in the following section.

The interactions between nanoparticles and soil components

The assembling of nanoparticles with soil particles

The assembly of NPs specifically refers to a process whereby the particles are organized with a repeating apparent morphology. The assembly of NPs has been studied for inorganic NPs, organic polymers, DNA, or proteins and employed in drug delivery, disease diagnosis and treatment, vaccines, luminescent materials, and flexible electronic devices. The most significant advantage of the assembling of NPs is to tailor their structure and thus their function. The assembling process of NPs also occurs in soil system. For example, natural organic matter (NOM) with non-amphiphilic, amphiphilic, and lipid fractions can form a hierarchical self-assembling system (Chilom et al., 2013). The assembling of NPs may contribute greatly to the generation of stable soil aggregates, in a process known as oriented attachment. The reason is that the assembling of NPs may remove the boundary between oriented NPs, decrease the total surface area and the surface free energy, and inhibit dissolution (Waychunas et al., 2005). Specifically, the heterogeneous assembling of NPs refers to the assembling among different types of NPs or among NPs and macroparticles, which could promote the formation of a more complex or ordered structure because of the typical anisotropic characteristics of NPs. These compactly formed soil aggregates are beneficial for the ecological stability of soil particles. Engineered simulation of this process may help in the development of slow-release fertilizers.

The surface coating of organic matter on nanoparticles

Soil is rich in natural organic matter (NOM), and NPs in the soil ecosystem will inevitably interact with NOM and form an ‘eco-corona.’ Because the sorption of NOM on NPs will significantly change their physical and chemical properties (Grillo et al., 2015), the sorption mechanisms have been widely discussed in previous studies. However, the interactions between NOM and NPs are considered very complicated and the reasons can be understood from the following (Fig. 3):

- (1) The NOM molecules contain various functional groups, such as carboxyl, hydroxyl, quinone, aldehyde, ketone, and sulfhydryl groups. These functional groups can act individually or simultaneously in NOM sorption through various mechanisms of electrostatic interaction, ligand exchange, hydrophobic interaction, hydrogen bonding, and cation bridging. Therefore, the types of NPs should be carefully considered in studying the sorption mechanism.

Fig. 3 Schematic summary of the interactions between soil and nanoparticles. (A) Properties in small circles are the soil factors that affect the behavior of nanoparticles (in the large circle); (B) effects of nanoparticles on soil properties. Abbreviations: EC, electricity conductivity; TOD, total oxygen demand; TSS, total suspended solids (Tan et al., 2018). From Tan W, Peralta-Videa JR and Gardea-Torresdey JL (2018) Interaction of titanium dioxide nanoparticles with soil components and plants: current knowledge and future research needs—A critical review. *Environmental Science: Nano* 5: 257–278. Reprinted with permission from Royal Society of Chemistry.

- (2) The sorption of NOM chemical components on NPs is selective, with some specific NOM molecules preferentially adsorbed. Investigations on the sorption selectivity of NOM molecules on common particles have not yet reached a common conclusion (Cai et al., 2015).
- (3) Studies on sorption are generally accompanied by a mathematical fitting of the apparent sorption curves. However, for NPs, the sorption curves do not follow the commonly applied models. Investigators have suggested that NPs may be dispersed after NOM sorption, and thus the sorption is not always thermally stable.
- (4) Considering the significant environmental roles of NPs, it may be more important to understand how NOM sorption affects their dispersion. It should also be noted that the mechanisms of NP dispersion are diverse, including surface coating, formation of micelles, and ‘unzipping’ (Singh et al., 2020). If the dispersion mechanisms by different NOM fractions are revealed, NP dispersion by NOM may be predicted better, or a strategy may be developed to obtain a highly effective dispersion reagent for NPs.

The embedding of nanoparticles in soil aggregates

The embedding of NPs in soil aggregates is different from the heterogeneous assembling of NPs and soil components. The assembling emphasizes the ordered and repeated morphology or structural units, while the embedding process is more like a random physical deposition of NPs in soil aggregates. Soil aggregates are the basic unit of soil structure and enhance aeration and drainage, reduce erosion and runoff, and promote rooting, soil fertility and productivity. The formation of soil aggregates is a comprehensive process that includes physical, chemical, and biological processes. Nanoparticles may be involved in all of these processes through agglomeration, sedimentation, co-precipitation, adsorption, and even biological digestion.

After being embedded in soil aggregates, the reactivity and mobility of NPs will greatly decrease. Because of the organic matter coating and particle blocking, accessibility of the surface of NPs, their dissolution, and surface oxidation are very low. Thus, the aging processes of NPs are greatly slowed. The embedded NPs cannot induce the generation of reactive oxygen species (ROS) and their toxicity is also significantly inhibited. However, it should be noted that the stability of NPs in the soil environment is increased. The release of NPs after the break-down of aggregates should be carefully evaluated for their consequent behavior and potential risks.

The impacts of nanoparticles on soil systems

Nanotechnology has shown its great potential in agricultural applications. However, investigators continue to identify the potential negative impacts of NPs. The debate on the double-edged effects of NPs will accompany the development of nanotechnology.

Beneficial application of nanoparticles in agricultural activities

By 2050, the human population is expected to be 9.8 billion. Food production will thus need to increase by 70% to feed this growing global population, while giving special consideration to the requirement for sustainable development of agricultural

production (Kopittke et al., 2019). Nanomaterials may serve as an efficient fertilizer or pesticide to achieve the goals of increased growth in crop yield and crop quality by improving plant mineral nutrition utilization compared with conventional fertilizer application. This may be possible by balancing the contents of essential macronutrients, mesonutrients, and micronutrients in crops, and by increasing the plant-beneficial soil microorganisms. Nutrients are generally applied to the soil (i.e., for root uptake) or to the plant leaves (i.e., foliar spray) to supplement nutrients in the soil (e.g., N (nitrogen), P (phosphorus), Mg (magnesium), Zn (zinc), Fe (iron), Mn (manganese), Si (silicon), Cu (copper)) or to control pests and diseases for crops. According to the current technology, the nano-fertilizers or pesticides mostly include the following four types.

- (1) Slow release of nano-fertilizers/pesticides. The NPs seem to be effective as a coating for reducing the rate of release and extending the retention time of macronutrient fertilizers or pesticides in the soil. For example, urea-modified hydroxyapatite NPs encapsulated into cavities of the soft wood of *Gliricidia sepium* (Jacq.) Steud showed an initial rapid release of N followed by a slower release in the next 60 days, and improved the yield of rice (*Oryza sativa* L.) more efficiently than conventional fertilizers (Kopittke et al., 2019). Due to the slow and continuous release of the embedded nutrients, NP fertilizers added to the roots can substantially increase both biomass and nutrient uptake compared with traditional fertilizers. Meanwhile, many other nutrients in the soil can be adsorbed on the surface of an NP coating because of the strong force of adsorption. Similarly, many NPs, such as Cu-, Zn- and Ag-based NPs have shown strong performances in controlling bacteria, fungi and insects, which implies the potential of NPs in protecting crops during growth or even storage.
- (2) Stabilized nano-fertilizers/pesticides. Here the stabilization is aimed at preventing fertilizers or pesticides from degradation. For instance, neem (*Azadirachtin indica* A. Juss., 1830) seed oil is known as a powerful natural insect antifeedant and a growth regulator. The effective component of azadirachtin can be easily degraded under the exposure of light, acid or alkaline media or by microorganisms. Using the nano-emulsion/solvent displacement and interfacial deposition method, Forim et al. (2013) synthesized a type of poly (ϵ -caprolactone) NP containing azadirachtin, with a solubility (260 mg L^{-1}), 13 times greater than natural azadirachtin. After 7 days of UV exposure, the photodegradation ratio of these neem NPs decreased from 100% to 10–55%. Similarly, rotenone, a botanical insecticide derived from the roots or rhizomes of tropical legumes, is limited in agricultural use due to its rapid degradation under ultraviolet light, low water solubility and strong toxicity to organisms. Using the N-(octadecanol-1-glycidyl ether)-O-sulfate chitosan nano micelles, Lao et al. (2010) successfully increased the water solubility of rotenone by 13,000 times and prolonged the release of the rotenone by 17 times.
- (3) Nanotechnology-facilitated transgene integration for crops. Recently, nanotechnologies have been developed to improve the stability of DNA during transgene integration for crops. Conjugates between positively charged NPs (e.g., gold NPs) and nucleic acid (e.g. poly-lysine) can overcome the cell wall barrier and be directed into the plant cell. The DNA is protected by NPs from enzymatic attack in the cytosol, but could be released into the nucleus (Moulick et al., 2020). The NP–DNA conjugate in combination with a magnetic field is entitled pollen magnetofection, and can be used to produce a stable transgenic plant even without tissue culture or regeneration (Moulick et al., 2020).
- (4) Fertilizers/pesticides hybrid. During growth and development, crops need a variety of nutrients rather than a single one. Thus, the demand for slow and sustainable release of various nutrients promotes the generation of hybrid nanofertilizers. At present, many researchers have formulated urea-hydroxyapatite nanohybrids for the slow release of nitrogen and phosphorus to plants. Tarafder et al. (2020) further incorporated copper, iron and zinc NPs into the urea-modified hydroxyapatite to enhance plant nutrition and disease resistance of the ladies' finger (*Abelmoschus esculentus* (L.) Moench).

Notably, various environmental factors such as temperature, soil pH and alkalinity may affect the solubility or chemical speciation (e.g., chelated, soluble, and bulk forms) of nano-fertilizers and consequently their availability to crops. In addition, the presence of organic matter may decrease the performance of inorganic components possibly through the formation of complexes or precipitates. Proper consideration of these factors will be beneficial for improving the performance of nano-fertilizers or pesticides in different scenarios.

The uptake of nanoparticles by soil organisms

The reactivity of NPs has brought a general concern that the application of NPs to soils might be involved with negative effects. For example, investigators have reported risks of NPs to soil enzymes, soil microorganisms and even soil animals. The main processes of NPs in the soil–organism system may include the adsorption of NPs to biological surfaces, the uptake and translocation of NPs inside organisms, and their storage in various tissues.

The NPs can be biologically available to soil organisms in two forms, the dissolved ions and the dispersed NPs. The uptake of dissolved ions is well-understood as passive or active transport. For NPs, in particular, their penetration through the bio-abiotic interface has attracted a great deal of research attention. Since the direct uptake of NPs by organisms has been confirmed, their risks should be carefully evaluated, considering their interactions with cell components, the generation of ROS, as well as the pollutants carried. Different techniques have been adopted to observe the penetration of NPs through cell walls and membranes. For example, SEM and TEM are the most commonly used instruments for observing the morphology of NPs outside or inside organisms. Using synchrotron-radiation micro-X-ray fluorescence, the crystalline phase and size of NPs can be identified after the internalization. Single particle-inductively coupled plasma-mass spectrometry and ^{14}C labeled methods were also successful to quantify the contents of metals or ^{14}C in plant tissues for metal-based NPs and carbon nanotubes, respectively.

It is easy to understand that NPs need to be dispersed before uptake. The NPs may be dispersed by engineered reagents, or natural chemicals such as DOM as discussed above. The dispersed NPs with sizes between 10 and 50 nm may enter biological cells via pinocytosis, while those larger than 100 nm may be absorbed by phagocytosis.

Nanoparticles as a two-blade sword to the soil system

As shown above, NPs have a great potential as fertilizers, pesticides or their additives for increasing crop production and to reduce adverse environmental problems caused by excess application of traditional fertilizers or pesticides. However, studies concerning the negative effects of NPs on soil organisms have increased year by year. Improper application of NPs may decrease the length of root, shrink root tips, result in considerable vacuolation or collapse of root epidermal and cortical cells (Nair and Chung, 2014), and reduce the abundance and diversity of soil bacterial and fungal communities (Liu et al., 2021). It is of great importance to establish strategies to overcome the negative impacts and preserve the beneficial effects of NPs to the soil system (Fig. 4). The strategies may include:

- (1) Control NPs at a safe concentration range. Almost all chemicals will show negative effects on organisms after exceeding a certain concentration. In addition, the varying environmental factors (e.g., pH values, electrolytes, temperature and organic matters) may also alter the threshold values through affecting the physicochemical properties of NPs. Full understanding of the underlying mechanisms of the biological effects of NPs should be the first step in proposing a threshold for a specific group of organisms under certain conditions. Continuous monitoring of the metabolites (e.g., siderophores) from plant roots in response to environmental stresses may also help to identify the potential risks of the system. Establishment of a database on detailed toxicity or ecotoxicity for different individuals (e.g., researchers, policy makers or product R&D people) may be the next step in the safe application of NPs.
- (2) Match positive NP-organism pairs. Because of differences in the sensitivity, tolerance and detoxification mechanisms of different organisms to even the same type of NPs, the threshold varies across different species of organisms. Positive effects of NPs may be achieved because of increased utilization efficiencies, or even through the 'hormesis' effect of NPs at low concentrations. Identifying the positive NP-organism pairs requires an extensive investigation of NP and organism combinations, which is time-consuming, costly, and labor-intensive. Modeling (such as hormetic dose-response, biotic ligand model, SAR or QSAR models) may be useful for calculating some critical values, such as concentrations producing no or small observed effects, and those that have half the maximal effect.
- (3) Use degradable NPs as carriers. Some matrixes or compositions of the nano-sized carriers may have antibacterial or anti-insect properties, and may change the microbial community in the soil with adverse effects on plant-microbe interactions. The investigation of biodegradable or photodegradable substances (e.g., chitosan or polymeric nanocarriers) can be one of the trends to develop nano-fertilizers or -pesticides in the near future.

Summary

The whole story regarding NPs in soil is about the balancing between their negative and positive effects. It cannot be over-emphasized that both NNPs and ENPs are dynamic particles, with varying reactivities during their aging, transport and interaction with soil components. Well-balanced NP properties are not only essential for nanotechnology management, but are also useful for nanotechnology applications in sustainable agriculture.

Abstract

Greenhouse gases (GHGs) alter the Earth's climate by absorbing energy in the lower atmosphere and re-emitting it. Anthropogenic emissions of carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O) contribute most to global warming. Soil is a major source and sink of GHGs. Here, the impact of soil chemistry, including soil organic matter, pH and nutrients on CO₂, CH₄ and N₂O emissions and the feedbacks of climate change, including warming, drying, precipitation and wildfires on soil chemistry are discussed.

Key points

- Soil chemistry significantly affects GHGs emissions.
- Climate changes also influence soil chemical properties.

Effects of soil chemistry on greenhouse gas emissions

Effects of soil chemistry on carbon dioxide emissions

Carbon dioxide (CO₂) is an important heat-trapping (greenhouse) gas, which is released through human activities such as deforestation and burning of fossil fuels, as well as natural processes such as respiration by organisms and volcanic eruptions. Since the beginning of the industrial era (1750), fossil fuel use, expansion of cultivated agriculture and forest clearance have led to an increase in atmospheric CO₂ from ~280 ppm to the current level of ~420 ppm (μmol mol⁻¹) in 2022. This change in atmospheric CO₂ concentrations is much larger than historic natural fluctuations over the past 20,000-year period (from the Last Glacial Maximum to 1750, from approximately 185 to 280 ppm). These elevated levels of CO₂ absorb and reradiate long-wave radiation, thereby retaining heat in the lower atmosphere and causing global warming. Carbon dioxide is the most important of the Earth's [long-lived greenhouse gases](#) contributing about two-thirds of the current [total energy imbalance](#). The average 2020 surface temperature was 0.98 °C warmer than that of the twentieth-century, and with temperature increases nearly double that in polar regions.

The present increase in atmospheric CO₂ is caused by anthropogenic emissions of CO₂. Land-use and land-use change are responsible for approximately 11% of all anthropogenic CO₂ emissions. Soils are a major source and sink of CO₂, hence approximately 10% of the atmosphere's CO₂ passes through terrestrial soils each year. The source and sink dynamics of CO₂ from soils depend on several environmental factors, such as ecosystem net primary productivity (carbon inputs), available soil water, soil temperature, soil organic matter, soil mineralogy and chemistry, and nutrient availability. Herein, we discuss the effects of soil chemistry, including soil organic matter, pH, and plant nutrients, on CO₂ emissions.

Soils are of particular importance in the atmospheric CO₂ budget as they store more organic carbon (1500 Gt) than the atmosphere (750 Gt) and plants (560 Gt) combined. Changes in the size of the soil C storage pool therefore can significantly affect atmospheric CO₂ concentrations. Soil organic carbon has decadal to centennial turnover times. Relatively inert (stable or recalcitrant) soil organic carbon is composed of molecules that are more or less resistant to further decomposition. A very small fraction of soil organic matter, and a small fraction of burnt biomass, are converted into inert forms. Natural processes and soil management practices may reduce or increase the amount of carbon stored in soil pools with turnover times on the order of tens to hundreds of years (e.g., black carbon—charcoal and biochar) and thus influence the evolution of atmospheric CO₂ over time. Conversion of natural vegetation to agriculture is a major source of CO₂, not only due to losses of plant biomass, but also increased decomposition

of soil organic matter caused by soil disturbance, and energy use associated with various agricultural practices. Conversely, the use of high yielding plant varieties, fertilizers, irrigation, residue management and reduced tillage can alleviate losses and enhance C uptake within managed areas. These processes have led to an increase of soil carbon and decrease of CO₂ emissions in some agricultural soils, especially those in arid and semiarid regions where irrigation greatly increases net primary productivity. Organic amendments may also contribute to increased CO₂ emissions. Despite all the benefits that organic amendments contribute to soil restoration, there is tremendous variability among the types of amendment. There is also considerable variability in organic matter composition and chemistry which can result in highly variable rates of organic matter decomposition, thereby altering the rates of CO₂ emission. The impact on CO₂ emissions was greater when applying organic amendments from pig manure compared with residue amendments from maize (*Zea mays* L.) cultivation.

Soil microbial activity has considerable effects on soil CO₂ emissions. Microbial activity is strongly influenced by soil pH. Therefore, management practices such as liming influence soil emissions by altering biological activity. In addition, CO₂ is released by the liming of acidic soils:

Alkaline soils have significantly higher CO₂-to-soil organic carbon ratios, and consequently soil organic carbon in alkaline soils appears less chemically stable with respect to microbial mineralization. Soil respiration decreased markedly from acid soil samples leading to lower CO₂ emissions.

In addition to soil pH, soil nutrient availability is an important factor regulating ecosystem net primary productivity (NPP), soil microbial activities and soil CO₂ emissions. Nitrogen (N) and phosphorous (P) are key nutrients that limit crop growth and microbial activities. Nitrogen availability is an important constraint on NPP at the global scale, although phosphorus and calcium may be more important limiting nutrients in many tropical and subtropical regions. Reactive nitrogen from burning of fossil fuels and biomass combustion (NO_x) and ammonia emitted by industry, animal husbandry and fertilizer use can act as a fertilizer for terrestrial plants thereby stimulating NPP. Nitrogen fertilization may enhance the formation of humified soil organic matter, which increases the residence time of carbon and decreases CO₂ emissions from soils. Conversely, nitrogen additions were shown to increase soil CO₂ efflux in a field experiment in Costa Rica, whereas N addition had no net effect or decreased soil CO₂ effluxes in China. It is generally acknowledged that P rather than N is the growth-limiting nutrient in many lowland tropical forests. Phosphorus additions to several tropical forests resulted in a strong increase in microbial biomass leading to an increase in the soil CO₂ efflux. The incorporation of crop residues (as opposed to burning) and application of inorganic fertilizers, green manures and animal wastes can be of great importance in maintaining soil fertility and hence ecosystem NPP. These practices can provide essential nutrients for agricultural crops and coupled with reductions in the burning of crop residues can reduce CO₂ emissions from soils to the atmosphere.

Effects of soil chemistry on methane emissions

Methane (CH₄), the second-most important greenhouse gas after carbon dioxide (CO₂), has contributed almost one quarter of the increase in cumulative radiative forcing for the major greenhouse gases (CO₂, CH₄, and N₂O) since 1750. Methane is also a precursor for tropospheric ozone (O₃)—both an air pollutant and greenhouse gas—influencing ozone background levels. Although methane is far less abundant in the atmosphere than CO₂, it absorbs infrared radiation more efficiently and, as a consequence, has a global warming potential (GWP) ~86 times stronger per unit mass than CO₂ on a 20-year timescale and 28-times more powerful on a 100-year basis. The atmospheric methane (CH₄) concentration reached 1895 nmol mol⁻¹ (ppb) in 2021, approximately 2.6 times greater than its estimated pre-industrial value of 722 ppb in 1750. The global network of surface observations over the past 3–4 decades indicates that methane went through a period of rapid growth from the 1980s to 1990s, almost stabilized from 1999 to 2006, and then renewed its rapid growth to the present. The overall increase in CH₄ concentration is attributable in large part to increased anthropogenic emissions arising primarily from agriculture (e.g., livestock production, rice (*Oryza sativa* L.) cultivation, biomass burning), fossil fuel production and use, waste disposal in landfills, and changes in natural methane fluxes due to climate change (e.g., melting of permafrost).

Global emissions from agriculture and waste disposal are estimated at 195 Tg CH₄ yr⁻¹, representing ~57% of total anthropogenic CH₄ emissions. Atmospheric methane concentrations are a balance between production and removal processes. Methane is removed from the atmosphere by reaction with the hydroxyl radical (·OH) in the troposphere, destruction by reactions with excited atomic oxygen and atomic chlorine (Cl) in the stratosphere and uptake and utilization in soils by methanotrophic bacteria (CH₄ oxidizers). Biogenic methane is the final product of the decomposition of organic matter by Archaea in anaerobic environments, such as water-saturated soils, wetlands, rice paddies, marine sediments, landfills, waste-water facilities, or inside animal intestines. In contrast, unsaturated oxic soils maybe a sink for atmospheric methane due to the presence of methanotrophic bacteria, which consume methane as a source of energy in which they oxidize the CH₄ to CO₂. Wetlands with temporally variable saturation can act as either a methane source or sink. Several soil factors influence methane emissions from soils, such as redox potential, alternative electron acceptors, substrate availability, temperature, diffusion, water availability, soil pH and salinity, fertilizer and manure additions. Below we discuss the impact of several soil chemistry parameters on methane emissions.

Soil organic carbon is an important component of the global carbon cycle and soil organic carbon dynamics strongly affect methane emissions. Readily mineralizable organic matter derived from primary production or organic amendments is the main electron donor resulting in methane formation in soils. Anaerobic conditions are necessary to facilitate the biochemical pathways of CH₄ production owing to the anaerobic nature of the methanogens responsible for CH₄ production by the process known as methanogenesis. Hydrogenotrophic (CH₄ production from H₂ and CO₂) and acetoclastic (CH₄ production from acetate as the

electron acceptor) methanogenesis are the most common pathways for CH_4 production in soils. During flooding of rice fields, the soil redox potential declines progressively as electron acceptors are consumed along the descending electron tower (e.g., O_2 , NO_3^- , Mn^{4+} , Fe^{3+} , SO_4^{2-} , CO_2). As soil organic matter is decomposed during periods of inundation, it releases electrons that facilitate the methanogenic process. Rice plants supply the microbes in soil and rhizosphere with organic substrates: about 30–60% of net photosynthate carbon is allocated to roots, and as much as 40–90% of this fraction is translocated into the soil as root exudates. Increasing C-substrate availability by the input of organic substances to the soil through root exudation and litter production stimulate methanogenesis and methane production. In contrast, a large portion of the CH_4 produced under anaerobic conditions may be oxidized in aerobic environments (e.g., water column of paddy fields or wetlands) before escaping to the atmosphere by the activity of methane-oxidizing bacteria, which utilize methane as a carbon and energy source. In this case, the organic matter does not directly affect methane-oxidizing bacteria, but does affect methane formation (i.e., methanogens) and other microbes in the environment, which have implications for the functioning of methane-oxidizing bacteria. The addition of organic materials, such as crop residues, to soils affects CH_4 oxidation in different ways, often depending on the C:N ratio. When the C:N ratio of the residues is low (i.e., high N content), CH_4 oxidation generally decreases. The increased release of ammonium increases ammonia oxidation, which inhibits the oxidation of CH_4 . Conversely, when the organic residues have a high C:N ratio, the CH_4 oxidation rate is not appreciably affected.

Soil pH is a crucial factor for regulating methane production in wetland rice soils in addition to the carbon supply and water regime. The optimal pH range for methanotrophic activity in soils is wide; there are reports of methanotrophic activity in acid (< 3.5) and alkaline (pH 9.5) soils. Soils generally have low methane production under acidic conditions. Moreover, the highest rates of CH_4 oxidation have been found in soils with near neutral pH conditions (~ 7.0). In general, nitrogen (N) and phosphorus (P) limitations are not frequently observed in methanogenesis. Methane production can be greatly attenuated when urea and manure are used as fertilizers. In flooded soils, CH_4 emissions were lower when ammonium sulfate was used as a fertilizer source compared to urea because of competition between sulfate-reducing bacteria and methanogens as electron acceptors. Fertilization with nitrate also decreases CH_4 emissions as the NO_3^- preferentially serves as an electron acceptor during the denitrification process. Notably, ammonium sulfate significantly reduced CH_4 emissions compared to the application of potassium nitrate in paddy fields.

The activity of methane-oxidizing bacteria largely depends on the presence of methane, therefore any factor that affects methane formation will consequently have implications for methane-oxidizing bacteria. Populations of methanotrophs in soils are affected by several environmental factors, most notably temperature, pH, type and concentration of N sources, and the concentrations of CH_4 and O_2 . The extent of the nutrient effects depends on whether Type I or Type II methane oxidizers predominate. Type I strains predominate in nutrient-rich environments, whereas the Type II strain can survive in environments where N is scarce. Methane monooxygenase requires copper (Cu) as a cofactor, and the amount of copper necessary for optimal activity varies within the community of methanotrophs. Overall, Type II methanotrophs are more active than Type I when Cu concentration is low and vice versa. While there are no conclusive results concerning potassium availability on methanotrophic activity, one report demonstrated a stimulating effect from the addition of potassium.

Effects of soil chemistry on nitrous oxide emissions

Nitrous oxide (N_2O) is the third most important greenhouse gas, after carbon dioxide (CO_2) and methane (CH_4), with a global warming potential ~ 298 times that of carbon dioxide on a 100-year time scale. It is also a potent ozone-depleting substance in the stratosphere, catalyzing the destruction of ozone in the stratosphere and contributing to the annual ozone hole in the polar regions. Ice-core measurements indicate that N_2O concentration in the atmosphere was nearly constant at about 270 ppbv in the 11,000 years prior to the beginning of the industrial era. Since the start of the industrial revolution, N_2O has increased from ~ 280 to 334 ppbv in 2021. Globally, soil ecosystems constitute the largest source of N_2O emissions, comprising approximately 65% of total N_2O emissions to the atmosphere. Specifically, 62% is derived from nitrogen fertilization and indirect emissions, 31% arises from manure management and 7% results from biomass burning. Almost all microbes and pathways involved in the biogeochemical cycling of nitrogen have the potential to produce N_2O as an intermediary product, and these processes are interrelated and interact to share intermediate products. These N_2O -generating processes include ammonia (hydroxylamine) oxidation, nitrifier denitrification, nitrite oxidation, heterotrophic denitrification, anaerobic ammonium oxidation (anammox) and dissimilatory nitrate reduction to ammonium (DNRA, or nitrate ammonification).

The key pathways involving N_2O production and consumption include nitrification and denitrification, with each of these processes mediated by specialized microbial assemblages. In the nitrification process, ammonium is first oxidized to nitrite, which is subsequently oxidized to nitrate. The N_2O is produced as a byproduct of the nitrification process. The first and rate-limiting step of the nitrification process, ammonia oxidation is carried out by ammonia oxidizing bacteria (AOB), archaea (AOA), or the recently discovered complete ammonia oxidation (comammox) bacteria. Nitrous oxide is also produced from denitrification, a process by which nitrate is progressively reduced to nitrite, nitric oxide, N_2O and N_2 under anaerobic conditions. The major abiotic determinants regulating N_2O production are soil oxygen levels, water content, pH, temperature, nitrate and nitrite concentrations, organic carbon content and micronutrient contents. Below, we discuss the impact of soil organic matter, pH and plant nutrients on nitrous oxide emissions.

Soil organic matter comprises the largest carbon stock in agroecosystems and plays a very important role in the global carbon and nitrogen cycles. The C:N ratio represents an important criterion for evaluating the quality of humus, and it also directly affects

N₂O emissions from soils. High soil N concentrations, especially those following fertilization, may enhance microbially-mediated N transformation processes leading to high N₂O emissions. The optimal C:N ratio of soil organic matter is considered to be about 10:1, whereas the ideal C:N ratio for compost is ~30 as the elevated carbon level provides sufficient food availability for microorganisms. Viewed globally, soils are the central link in the organic matter biotransformation chain with significant gaseous C and N end-products. Several studies report that N₂O fluxes increased after the application of residues, with low C:N residues releasing more N₂O than residues with high C:N ratios. The addition of organic substances has a positive effect on soil nitrification and the autotrophic nitrifier population. Similarly, organic amendments significantly increased the abundance of AOA and stimulated the growth of AOB in agricultural and riparian zone soils. The amount of organic C, as a substrate for bacteria metabolism, is a primary determinant regulating the N₂:N₂O ratio of denitrification. Large concentrations of labile soil organic carbon increase microbial activity resulting in the consumption of N₂O to produce N₂, thereby increasing the N₂:N₂O ratio.

Soil pH is another important factor influencing N₂O emissions. Several studies have demonstrated that the abundance and structure of nitrogen-cycling genes, and the rates of nitrification and denitrification, are strongly regulated by soil pH. Soil pH is a vital factor influencing the niche differentiation of the autotrophic nitrifiers AOA, AOB and comammox bacteria. The AOA generally dominate ammonia oxidation in acidic soils and either AOA or AOB may dominate ammonia oxidation in slightly acid to neutral pH soils. In contrast, the role of pH on the distribution of the recently discovered comammox bacteria are unknown. While the contribution of ammonia oxidation to N₂O emissions remains ambiguous, a meta-analysis of 100+ isotope dilution studies determined a slightly negative correlation between gross nitrification rates and soil pH. Autotrophic nitrification and the resulting N₂O flux are limited at soil pH values less than 4.5. Soil pH also affects the N₂:N₂O ratio, with N₂O/(N₂ + N₂O) having a significant negative relationship with soil pH within the normal range (pH = 5–8) of agricultural soils. Notably, a global meta-analysis of field experiments revealed that the amount of N₂O substantially increased in soils with lower pH values. A possible mechanism for the positive effect of acidity on N₂O emissions was attributed to the inhibition of nitrous oxide reductase through the disruption of enzyme assembly in the periplasm.

All forms of N inputs to agricultural soils, such as inorganic N fertilizer and organic N sources in the form of manures, slurry, legumes or post-harvest crop residues, represent a potential contribution of N substrates for subsequent N₂O emissions. The influence of fertilizer on N₂O emissions is a function of the fertilizer type (e.g., organic, NH₄⁺ or NO₃⁻), the amount, and timing of application. A meta-analysis revealed a greater loss of N₂O from urea than from (NH₄)₂SO₄ (ammonium sulfate) fertilizer treatments. The greater is the amount of ammonium in the fertilizer, the greater is the potential for nitrification, which is a source of N₂O emissions. Furthermore, the loss of N₂O can increase because the nitrite formed during the nitrification process can be used as an electron acceptor during denitrification, if O₂ is limited. Thus, both nitrification and denitrification are sources of N₂O under aerobic vs anaerobic conditions, respectively. Emissions of N₂O are greater when nitrate concentration in the soil is high. However, several studies indicate that large soil nitrate concentrations inhibit the reduction of N₂O to N₂, thereby resulting in a higher yield of N₂O. Soil nitrate concentrations as high as 277 µg N g⁻¹ soil inhibited N₂O reductase activity, which reduced the conversion of N₂O to N₂ and resulted in lower N₂:N₂O ratios in sandy and silt loam soils. In addition, denitrification enzymes require a variety of metal cofactors, including Mo (molybdenum), Fe (iron), Cu and Zn (zinc). The absolute requirement of nitrous oxide reductase (the enzyme that reduces N₂O to N₂) for Cu cofactors accounts for the critical role of this micro-nutrient in regulating the denitrification process. Thus, several soil chemical properties regulate N₂O emissions from soils, with important implications for agricultural and environmental management.

Impact of climate change on soil chemistry

Effects of warming on soil chemistry

Global warming is expected to lead to an increased global surface temperature of between 2.1 °C and 3.5 °C over the 21st century, due to greenhouse gas emissions from human activities. Warming significantly affects plant growth, organism activity and rates of chemical reactions making soil chemistry highly responsive to warming. Soil organic C, arguably the most important component in soils, comprises 1500 Gt of carbon stored in soils, which is twice that contained in the atmosphere. Warming increases plant photosynthesis and water-use efficiency, which has the potential to enhance CO₂-fixation from the atmosphere and increase C storage in soils. On the other hand, increased plant C inputs to soil may create a soil priming effect, thereby enhancing soil organic C decomposition and CO₂ emission back to the atmosphere. Therefore, several interacting feedbacks may offset the increased soil organic C from plant C inputs making conclusions somewhat tenuous.

Several global-scale studies contend that the size of the overall soil organic C pool will not change appreciably, even though soil C fluxes and biogeochemical C cycling are expected to accelerate (Kuzakov et al., 2019). Soil organic C consists of diverse compounds that have simple (e.g., glucose) to complex (e.g., lignin) chemical structures, which generally correspond to a gradient of labile to recalcitrant C compounds. The temperature sensitivity of organic carbon decomposition and feedbacks to warming depend on the degree of warming and the chemical composition of the organic compounds. In general, higher temperatures are expected to cause greater decomposition of soil organic C by a combination of biotic and abiotic processes. In addition to greatly affecting the rate of decomposition of soil labile C, warming is reported to alter the rate of decomposition of more recalcitrant C compounds, thereby leading to a positive feedback in response to climate change (Frey et al., 2013). Subsoil horizons contain more than half of globally stored soil organic C, which is considered to be relatively stable under warming due to physical and chemical stabilization mechanisms arising from interactions with the soil colloidal fraction. However, in some specific ecosystems, such as

alpine grasslands, subsoil organic C is also sensitive to warming. Root exudate inputs to subsoil horizons are associated with deepening root systems that could potentially increase soil organic C fractions, such as lipids and sugars, and decrease other C fractions, such as phenols and lignin (Jia et al., 2019). To assess ecosystem and soil carbon storage rigorously in response to climate change, it is necessary to critically examine plant carbon allocation (above-ground vs below-ground) and the dynamics of subsoil organic carbon pools.

Soil N biogeochemical cycling is intimately linked to soil C cycling, as the soil C:N stoichiometry is well constrained to a narrow range across various terrestrial ecosystems. Hence, the response of soil organic C to warming has a similar pattern to that of organic N; however, warming also affects soil inorganic N cycling and N availability. Effects of warming on soil N transformations are important because forest and agricultural ecosystems often suffer from N limitation. As mentioned previously, increased plant growth with warming will increase plant demand for available N, which may accelerate N limitation in terrestrial ecosystems, termed progressive nitrogen limitation. A recent evaluation of global warming effects on N-cycling revealed a shift in microbially-regulated processes from N immobilization to enhanced N mineralization, nitrification and denitrification (Dai et al., 2020). The increased potential for nitrification and denitrification pose a further risk for the loss of inorganic N (e.g., leaching, runoff and N_2/N_2O emissions) from terrestrial ecosystems, again accelerating N limitation in terrestrial ecosystems.

Warming also affects soil chemical properties including pH and mineral nutrient availability, such as K^+ (potassium), Ca^{2+} (calcium) and Mg^{2+} (magnesium). Organic acids and H^+ secreted by plant roots under warmer conditions can decrease soil pH, despite an increase in net primary production. Warming also affects rates of mineral weathering and nutrient mobilization by affecting plant root and microbial pathways (e.g., through respiration and root extension). Moreover, increased CO_2 concentrations accelerate mineral weathering and the release nutrient cations, such as K^{2+} , Ca^{2+} and Mg^{2+} . Furthermore, root extension may contribute to mineral weathering by physical and biochemical pathways. However, the impact of higher temperature on mineral weathering is relatively weak compared to other climate change events, such as precipitation, drying and fire. The nutrient elements released from primary minerals can also be quickly taken up by plants, thereby offsetting the increase in soil mineral nutrient pools due to enhanced chemical weathering.

Effects of drying on soil chemistry

Climate change may also induce significant drying effects in some geographical regions. Drying is a serious threat to ecosystem and agricultural productivity, and ecosystem stability, and pronounced drying may lead to widespread desertification. The percentage of land worldwide subjected to drying will rapidly increase as atmospheric temperatures rise. Under warming, the intensity, duration and frequency of droughts are rapidly increasing. The drylands are mainly distributed in the western United States, north and east Africa, Australia, and central Asia, and cover over ~45% of Earth's land surface. In humid regions, drying may cause a shift in ecosystems, such as transformation of forests to woodlands to grasslands to deserts, resulting in a large loss of biodiversity.

Drying has several prominent effects on soil chemical properties related to soil moisture, such as redox potential, salinity, alkalinity and pH. Drying causes greater oxygen concentrations and would be expected to reduce CH_4 production, denitrification and sulfate reduction in soils. Soil salinization and alkalization often occur in drylands and poorly managed irrigated lands because salts are inadequately leached or concentrate in the rooting zone due to capillary rise of water from subsoil or groundwater sources. Evaporation and transpiration further concentrate soluble salts (e.g., Na^+) in surface soils inducing soil salinization and alkalization. The high ionic strength of saline soils hinders plant availability of water due to the low osmotic potential of saline waters. Soils experiencing salinization or alkalization generally have high soil pH (pH > 8.5), which reduces the availability of several trace nutrient metals (e.g., Fe, Mn (manganese), Cu, Zn).

Ecosystem and soil drying may decouple the C, N and P biogeochemical cycles and change soil organic C, N and P pools and fluxes. Drying usually reduces primary ecosystem production as moisture becomes the limiting plant growth factor in many arid and semi-arid climates. Decreased plant cover and associated soil biological processes result in decreased returns of plant litter and root exudates to soils, causing a decrease in soil organic matter. Drying also reduces the activity of soil microorganisms and small fauna that control soil nutrient cycling. Inhibition of soil microbial activity by moisture limitation will decrease microbially-regulated organic C decomposition and nutrient mineralization. While the contribution of microorganisms to soil organic C is less than plant C inputs, the low C:N ratio of microbial biomass has a disproportional effect on nutrient cycling. Similarly, soil drying may have a negative effect on total soil N concentration as biological processes, such as photosynthesis, decomposition and N fixation, are very low compared to humid regions. The decrease in soil organic C and total N pools with climate drying becomes more prominent with increasing intensity, duration and frequency of drought, increasing the potential for a collapse of ecosystems into a state of desertification.

Drying favors the dominance of physical processes, e.g., rock weathering, leading to the release of rock-derived nutrients, especially P, K, Ca and Mg (Delgado-Baquerizo et al., 2013). With water-limited plant growth, plant uptake of nutrients is very low, which also leads to the accumulation of inorganic P and mineral nutrients in arid-region soils. Thus, drying may have a positive effect on the availability of inorganic P and base cations, whereas it has a negative effect on soil organic C and N concentrations. Soil micronutrients such as iron (Fe), manganese (Mn), copper (Cu) and zinc (Zn) play an important role in organism growth and ecosystem function. A recent study found that globally, except for Antarctica, the availability of soil Fe, Mn, Cu and Zn in drylands is less than that in humid-region soils (Moreno-Jiménez et al., 2019). Drying decreases the availability of many micronutrients by increasing soil pH. The precipitation of micronutrients with -OH are more prominent in soils with high pH rendering them less

available to plants. The change in micronutrient availability in soil due to global warming induced drying may further exacerbate food production and security, and the diversity of plants and soil organisms in arid and semi-arid ecosystems worldwide.

Effects of precipitation on soil chemistry

Heavy precipitation has appreciable effects on soil chemistry that depend on the frequency and magnitude of extreme rainfall events. A direct effect of heavy precipitation on soil chemistry is the alteration of soil moisture related properties, such as plant nutrient availability, soil pH and redox potential. Soil base cations (e.g., K^+ , Na^+ , Ca^{2+} , Mg^{2+}) constitute a source of soil alkalinity and pH buffering capacity. Heavy precipitation increases water infiltration causing enhanced leaching of base cations that may result in soil acidification (decreasing soil pH). A decrease in soil pH will have a corresponding effect on nutrient availability, such as decreased base cations, potentially increased micronutrients and inorganic P, which has optimum availability in the pH range of 6–7. In addition, higher precipitation decreases soil N availability by increased nitrate leaching, whereas phosphate that is predominantly bound to soil particles is lost by increased soil runoff and erosion. Heavier rainfall events can cause serious soil erosion, especially in arid regions where lack of soil cover cannot protect the topsoil from raindrop impact which destroys surface soil structure and reduces infiltration. Soil erosion removes the surface soil, which has the highest organic matter, nutrient and biological diversity and activity, thereby causing considerable degradation in soil quality and productivity. Further, the nutrients and organic matter eroded from soils accumulate in surface waters where they contribute to eutrophication.

If the magnitude of precipitation exceeds the hydraulic conductivity of various soil horizons, the soils may become water saturated leading to a lack of oxygen and low redox potential. Reduced redox potential under water-saturation affects the speciation of several soil elements, influencing nutrient cycling, nutrient availability and elemental toxicity. The reduction of nitrate, sulfate, Fe, Mn, metal(loids) (e.g., As (arsenic) and Cr (chromium)), methane production and anaerobic decomposition of soil organic matter tend to increase after heavy precipitation. Chemical weathering is generally increased by “excess” precipitation and leaching, thereby leading to increased clay formation. Soil desiccation favors the formation of crystalline clay minerals at the expense of noncrystalline or nanocrystalline colloids, which has profound effects on soil mineral reactivity with respect to sorption reactions and soil organic matter stabilization.

In several regions of the world, increased precipitation will result in increased acid deposition to ecosystems and soils. Acid deposition contains large concentrations of sulfuric and nitric acids, and ammonium that can oxidize to nitric acid, resulting in pH values often in the 4.0–4.5 range, but as low as 2.0. Acid deposition enhances soil acidification through H^+ inputs into soils, which at pH values less than 5 solubilizes aluminum that can become toxic to sensitive plants. The increased amount of acidic cations (e.g., H^+ and Al^{3+}) facilitates the exchange of base cations (e.g., Ca^{2+} and Mg^{2+}) from soil colloids, and with the charge balancing anions (e.g., SO_4^{2-} and NO_3^-) accelerates the leaching of the exchangeable base cations. The increased concentrations of H^+ and Al^{3+} and decreased concentrations of base cations limit soil productivity. In general, soil has a buffering capacity (e.g., exchangeable bases) that offsets the acidity from acidic deposition by neutralizing such inputs. The buffering capacity varies with soil type, with a strong dependence on the amount and type of clay minerals and organic matter content. For example, soils dominated by permanently charged minerals (2:1 clay minerals) and large organic matter content are more resistant to acid deposition (i.e., more strongly buffered) than soils dominated by variable charge minerals (e.g., 1:1 clay minerals and iron–aluminum (hydr)oxides) and small organic matter concentrations. In addition, acid deposition has less effect on alkaline than acid soils due to their inherent alkalinity (acid-neutralizing capacity). Finally, the acid inputs from deposition can increase mineral weathering compared to non-polluted precipitation resulting in increased clay formation and the release of rock-derived nutrients.

Effects of wildfire on soil chemistry

Climate change increases the risk of hot and dry weather that can result in prolonged droughts. This dramatically increases the intensity and frequency of wildfire events in forest ecosystems, which are of prime importance for water and soil protection, species conservation and carbon sequestration. Currently, about 50–85 million hectares of global forestlands burn each year due to wildfires (Alonso-Canas and Chuvieco, 2015). Plant biomass, leaf litter and a portion of organic matter at the soil surface are consumed by high-temperature burning and converted into CO_2 , H_2O and other gases, and it also generate a layer of ash composed largely of mineral materials at the soil surface. The ash layer typically has a very high pH (>8–9) and a high content of soluble cations and anions that includes several plant nutrients (e.g., P, Ca, K, etc.).

As fire intensity and temperature increase, soil and plant organic carbon undergoes transformations from slight distillation to carbonization and pyrolysis to complete oxidation. A significant loss in organic carbon content starts at 200–250 °C, with progressively larger losses up to a temperature of ~460 °C (Giovannini et al., 1988). Thus, it is typical to find a remarkable loss in ecosystem and soil carbon stocks because of high-intensity fires. Incomplete combustion generates recalcitrant products, such as black carbon, which is relatively stable compared to soil organic C compounds. In fact, low intensity fires may actually increase the soil organic C content by introducing incompletely burnt plant materials (e.g., charcoal) into the soil.

Similarly, wildfire leads to a significant loss of soil organic N by conversion into gaseous N_2 , NH_3 , N_2O and NO_x as a result of volatilization, and in some cases N limitation may be found in post-fire forest ecosystems. A global meta-analysis indicated that wildfire reduces soil C and N in surface mineral soil layers with the losses depending on forest ecosystem types and fire characteristics (Pellegrini et al., 2018). Wildfire affects soil organic C and N when soil temperatures exceed ~200 °C during combustion, but normally the temperatures only become appreciably elevated in the upper 2–3 cm of the soil (Alexis et al., 2007). Elevated soil

Table 1 Wildfire effects on soil pH, organic C, total N, total P and micronutrients.

Soil chemical property	Fire effects and mechanisms
Soil organic C	Wildfire volatilizes plant biomass, litter residues and soil organic C leading to a decrease in soil organic C; Incomplete combustion generates recalcitrant products, such as black carbon and charcoal; Increased C and N pools after lower intensity fires are observed because of the incorporation of unburned or partially unburned slash fragments into the soil layer
Soil pH, base cations and electrical conductivity	Wildfire burns much of organic biomass and leaves soluble minerals in the ash layer thereby increasing soil pH, base cations (K, Na, Ca, Mg) and electrical conductivity
Soil total N	Similar to organic C, soil organic nitrogen is converted to N_2 , NH_3 , N_2O and NO_x as a result of volatilization. This may lead to N limitation in forest ecosystems following wildfires
Soil total P	Mineral P is not easily volatilized, but rather accumulates in the ash layer leading to a significant increase of inorganic total and available P concentrations. The increase of pH in highly acidic soils further increases PO_4^{3-} availability
Soil total micronutrients	Soil micronutrients, such as Fe, Mn, Cu, Zn, are not easily volatilized and therefore accumulate in ash layer. Changes in soil pH may either increase or decrease micronutrient availability depending the optimum pH for each micronutrient's availability

temperature mainly affects the soil organic layer with temperatures reaching only 50 °C in the mineral layer, even when temperatures in the organic layer exceed 500 °C (Trammell et al., 2004). As a result, only small changes in mineral soil carbon and nitrogen pools generally occur, even following high intensity fires.

Forest fires have several effects on total and available P pools, converting the organic pool of soil P to orthophosphate, a process termed pyromineralization. Mineral P is not easily volatilized and therefore accumulates in the ash layer at the soil surface, leading to a significant increase of inorganic P concentrations (Butler et al., 2018). Since the peak in P availability occurs around pH 6.5, fire-induced changes in soil pH, especially in acid soils, has a positive effect on soil P availability. Although wildfire results in an enrichment of available P, leaching and runoff may cause a loss of P from forest ecosystems after fire events. In tropical and subtropical regions, the fire-released P is immobilized by soil Fe and Al (hydr)oxides leading to a decrease in P availability to plants. Overall, wildfires have a destructive effect on forest ecosystems and several soil chemical properties, and the negative effects increase as fire intensity and frequency increase (Table 1). The short-term effects of wildfire are significantly larger than other climate change effects, such as warming, drying and extreme precipitation events. The recovery of vegetation and soil properties may take several decades, especially if high temperatures and drought conditions further hinder forest ecosystem recovery.

Concluding remarks and future research

Soil chemistry such as soil pH, nutrient availability and organic matter affect the emissions of greenhouse gases such as CO_2 , CH_4 and N_2O . These changes cause a variety of climate and weather-related events: warming, drying, precipitation and fire. In turn, the events give considerable or slight feedback to soil chemical properties in different ways. Here, we point out some future research that will help us to understand global warming effects and climate change management. Climate change usually occurs concurrently and therefore soils suffer from multiple pressures. However, we know little about the reaction of soil chemistry to multiple climate change factors which reveal the real-world condition. We lack a unified perspective of the variation in soil chemistry at global, continental or supracontinental scale, covering diverse climates, vegetation and soil types, as every soil on the earth is affected by global warming. Correspondingly, the emissions of CO_2 , CH_4 and N_2O under climate change and their deterministic factors at the global scale require systematic investigation. Global warming may last for decades or centuries, while most findings are based on short-term experiments, e.g., microcosms and field trials (<10 years). Long-term effects of climate changes on soil chemistry based on longer-term field observations or prediction models will have important implications for the maintenance of ecosystem function, food production and sustainable management.

EDITORS BIOGRAPHY

Michael J Goss, PhD, MSc, BSc, is a professor emeritus in the School of Environmental Sciences at the University of Guelph. Before taking on the joint editor-in-chief responsibilities with Margaret Oliver, he held a similar position for *Soil Use and Management*, a journal of the British Society of Soil Science of which he is an honorary fellow. He was an inaugural member of the European Society for Agronomy. Michael started his career at the Letcombe Laboratory before moving to Rothamsted Experimental Station and the Macaulay Land Use Research Institute (now the James Hutton Research Institute). In 1990 he was appointed to the Research Chair in Land Stewardship at the University of Guelph and in 2005 became the director of its Regional Campus near Ottawa.

Michael's research has covered soil plant relations, soil management, and agriculture's footprint on the environment. His focus has been on the physical properties of soil and their impacts on root growth, which he showed to be influenced by the role of the root cap. He broadened his approach to include the effects of tillage and land drainage on root exploration. This work stimulated his interest in the transport of materials, such as plant nutrients, pathogenic microbes, antibiotics, and biologically active compounds through the soil and their contamination of water resources. Michael's knowledge in this field resulted in his involvement in the public inquiry into the death of seven people, including children, from a microbially contaminated drinking water supply. He contributed, both to the investigation into how the contamination occurred and if any fault could be attributed to local agricultural practices, and to how to prevent future events.

Michael also developed an interest in the interrelationships between soil microbes and root systems, particularly the tripartite symbiosis between roots of legumes, mycorrhizal fungi, and rhizobia. He has been an energetic member of collaborative research programs in France and Germany, and in Portugal, where he continues his interest in the role of mycorrhiza in sustainable land management.

Michael has authored more than 180 publications including two books, one in its 2nd edition, and edited two others.

Margaret Ann Oliver (BSc, PhD)

Margaret's interest in soil began in her penultimate year at school when learning about different types of soil and their formation. She chose the University of Bristol, United Kingdom for her first degree because the geography course offered soil science and she was also able to do a degree in geology alongside. Her love for both subjects remains undiminished. She did her PhD in soil spatial analysis at the University of Birmingham. Her early research focused on the multivariate and geostatistical analysis of soil data, which she continued to use in various research projects. Her research interests expanded to include the application of a wide range of numerical and geostatistical methods to soil and other data including pollen counts, forestry, radon emission, remotely sensed imagery, precision agriculture, and the incidence of childhood cancer. Her specific interests have been in sample design for spatial analysis and eventual mapping, risk analysis associated with prescribed thresholds in relation to soil pollutants or deficiencies of crop nutrients, and the relations between different scales of spatial variation. Her most

recent research was in the field of precision agriculture. At both the Universities of Birmingham and Reading, she taught topics in soil science, statistical methods, and spatial analysis. At Reading she had a research group working on various projects such as imagery, sampling and mapping, precision agriculture, and human health.

She has published more than 100 academic papers and has made several contributions to books. She is the co-author of three books: *Statistical Methods in Soil and Land Resource Survey*, Oxford University Press (Webster, R and Oliver, M. A. 1990); *Geostatistics for Environmental Scientists*, Second Edition, John Wiley & Sons (Webster, R and Oliver, M. A. 2007), and *How to do the Basic Steps in Geostatistics: The Variogram and Kriging*, Springer, Dordrecht (Oliver, M.A. & Webster, R.2015). She has edited two books: *Geostatistical Applications for Precision Agriculture* (Springer, Dordrecht, 2010) and *Precision Agriculture for Sustainability and Environmental Protection* (Earthscan from Routledge, 2013).

Margaret retired officially from Reading in 2004, but as yet has not managed to escape from academia. She has retained a link and a base at the University as a visiting professor since January 2005. After retirement, she developed and taught geostatistics courses to outside groups for several years. She then started on the long path of editorial work, as an associate editor of the *European Journal of Soil Science* and eventually the editor-in-chief, assistant editor of *Mathematical Geosciences*, co-editor of *Precision Agriculture* with John Stafford, and finally the editor-in-chief of the *Encyclopedia of Soils in the Environment* with Michael Goss.

Margaret was made an honorary member of the British Society of Soil Science in 2021 to reflect her commitment to soil science through fellow research, teaching, and editorial work. She was honored by the Pedometrics Commission of the International Union of Soil Science by having an award named after her in 2015. It is the Margaret Oliver award for young pedometricians.

FOREWORD

Soil is the porous “skin” on the surface of the Earth that has formed over thousands of years of weathering, comprising minerals, organisms (both dead and alive), water, and air. Soil is more than just the sum of its parts. It serves several crucial ecological functions, from food and fiber production to water storage and purification to waste decomposition.

Increasingly we understand that everything is connected, and that soil is a “Critical Zone” that intersects with the hydrosphere (water), lithosphere (minerals), atmosphere (air), and biosphere (all living organisms). To quote Daniel Hillel, the 2012 World Food Prize laureate and editor of the First Edition of *The Encyclopedia of Soils in the Environment*, “[Soil] is the crucible of terrestrial life, within which biological productivity is generated and sustained...Our civilization depends on the soil...” He also promoted the importance of understanding soil to manage it effectively. This revised and reorganized second edition of the Encyclopedia aims to reflect the changing status of soil in the world. Within these five volumes, over 724 experts from many countries have provided updated, easy-to-understand chapters on soil, its properties, and its role in the environment to affect climate change, plant productivity, human health, and biodiversity.

Many technological advances have been made since the first edition of this encyclopedia that has allowed us to investigate soil physical, chemical, and especially biological properties more precisely, enabling us to identify and understand their roles in ecosystem services. The study of soils, especially in the environmental context, is critical to meeting the challenges of feeding, clothing, and cleaning up the world. The information presented in these volumes will be useful to many, including soil and environmental scientists, policymakers, land managers, educators, students, and anyone interested in learning more about soil.

Soil is under considerable threat from many sources—building and infrastructure, climate change, population pressure, and pollution, yet it is vital to agronomic productivity and continues to provide critical ecosystem services. Society needs to be engaged in how soil is managed and conserved. Most natural scientists are very dedicated and generous, including all of the authors in this Encyclopedia who have freely given their time to make these volumes so comprehensive. The study of soil, while often challenging, is fascinating—soil is a beautiful earthy material that can delight our senses with its variegated colors, gritty to smooth textures, and especially its characteristic aroma when freshly turned. Perhaps that is why gardeners and even some farmers tend to overwork their soil to its detriment—it *just feels good to get your hands in the dirt!*

Soil science is one of the most exciting, interesting, and rewarding disciplines, largely because it is multi-dimensional and interdisciplinary, basic and applied. It affects all of our lives. Thus, I encourage you to peruse these volumes and discover all kinds of interesting aspects of soil in the environment.

April Ulery

Former President, Soil Science Society of America
Professor, Soil & Environmental Sciences
New Mexico State University
Las Cruces, NM
The United States

PREFACE

This second edition of the *Encyclopedia of Soils in the Environment* follows in the footsteps of a highly rated first edition overseen by Professor Daniel Hillel as editor in chief, ably assisted by six editors. That edition provided a very valuable resource on the “state-of-the-art” in soil science in the context of the environment in the closing years of the twentieth century and the first three years of the current century. It set a standard that the editorial team for the second edition has aimed to match. The soil and environmental sciences have made huge strides in the almost 20 years since the first edition was published, and the new team has had to embrace these developments while retaining the basic components of these sciences. The project has taken 4 years to complete. It began with the appointment of the two editors-in-chief, professors Michael J. Goss and Margaret A. Oliver, followed by that of the nine subject editors and a pedology adviser.

The project was in its infancy (a few months only) when COVID-19 struck. The editors-in-chief discussed the format and structure of the second edition around the time that the first “lockdowns” around the world were being introduced. The first edition was alphabetically organized, whereas we decided to have a section-oriented approach in this edition, which we hope gives a more structured feel for the various topics embraced. The principal sections are soil biology, soil chemistry, the soil environment and its management, pedology (the origins and development of soil), pedometrics (the application of mathematics and statistics to soil), and soil physics. We were able to give our full attention to this development and to the selection of the scientists to join us on the road ahead. Furthermore, we were fortunate to choose a team that has maintained its enthusiasm despite the many tribulations we have faced along this path. The team comprises Jane Blagodatskaya and Adrian Unc (biology and microbiology), Siobhan Staunton and Baoshan Xing (chemistry), Karin Müller and Christina Siebe (environment and management), Rupert Bäumler (pedology), Uta Stockmann and Margaret Oliver (pedometrics), and Paul Hallett and Dani Or (physics). The editorial board has been mindful in their choice of subjects of the need for basic soil science and for state-of-the-art developments, with the aim that the audience for these volumes can be as large as possible.

During the gestation period of the Encyclopedia, methods of working for those in academia were turned on their heads. The change from “face-to-face” teaching to formulating and establishing online courses, initially for lockdown periods but then for much of the next 2 years, had huge consequences for academic staff worldwide. This meant that they had less time to devote to outside activities, such as writing chapters for an encyclopedia. As a result, some authors were unable to complete their chapters in time, leaving a few unfortunate gaps. The whole team has done as much as they can to limit any adverse effects, but we ask readers to appreciate the struggle that authors have had with illness (personal, within their families and work colleagues) and a great increase in their workload. Despite this, we are presenting a comprehensive document that should stand the test of the next 20 years of soils in the environment.

This century has seen an almost unprecedented interest in the soil and environmental sciences. It has been triggered not only by issues that the Earth is facing from global climate change, increasing population pressure, soil and land degradation, and food insecurity but also by the many new and sophisticated methods available, such as the DNA determination of microbial populations and their functional capabilities, proximal sensing, machine learning methods, and an ever-increasing array of technological tools. These developments have greatly increased our knowledge and appreciation of the complexity of soils, which has changed our understanding of some well-established aspects of the science. The soil and its environment are at the critical interface of the atmosphere, biosphere, hydrosphere, and lithosphere. They deserve to be taken seriously by the international community in the same way that air and water have been. Governments are now paying attention

to the soil and environment, and a legal and governance framework is emerging to look after these parts of our life support resources.

We have aimed, through our editing of chapters, to make the language of the chapters accessible to all, regardless of educational background. This does not mean that we have diminished the scientific content, but that readers should be able to gain the foothold they desire in these subjects to progress to greater knowledge and understanding of them. We have retained the overview of soil written by Daniel Hillel for the First Edition, first to honor his great contribution to soil science and second to demonstrate the significance of soil. It follows this Preface.

*Michael J. Goss
Margaret A. Oliver*

SOIL

The term “soil” refers to the weathered and fragmented outer layer of our planet’s land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly varied body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth’s rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body—typically not much more than one meter thick and often less than that. Yet it is the fount of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity’s utter dependence on the soil, ancient peoples, who lived in greater closeness to nature than many of us today, actually revered the soil. It was not only their source of livelihood but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramics, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from “adama,” meaning soil. The name given to the first earthling’s mate was Hava (Eve, in transliteration), meaning “living” or “life-giving.” Together, therefore, Adam and Eve signified quite literally “Soil and Life.”

The same powerful metaphor is echoed in the Latin name for human species—Homo, derived from humus, the material of the soil. Hence, the adjective “human” also implies “of the soil.” Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called developed countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity—all these processes, which involve the soil directly or indirectly, have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as “dirt.” Some fastidious parents prohibit their children from playing in the mud and hurry to wash their “soiled” hands when the children nonetheless obey an innate instinct to do so. Thus, soil is devalued and treated as unclean though it is the terrestrial realm’s principal medium of purification, wherein wastes are decomposed and nature’s productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil’s intricate passages, and plant roots extract

water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface—whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of diseases and have then been buried in the soil, yet no major human disease is transmitted by it. The term antibiotic was coined by soil microbiologists who, as a consequence of their studies of soil bacteria, specifically actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the Earth's greenhouse effect and to global warming. On the other hand, the opposite act of afforestation and soil enrichment with organic matter, such as can be achieved through conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon thus helps to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called "desertification," already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information—accessible to students, scientists, practitioners, and the general public—about the soil in all its manifestations in nature and in relation to the life of humans.

Daniel Hillel
May 2004

LIST OF CONTRIBUTORS FOR VOLUME 3

Stefan Abel
Independent Researcher

CL Acharya
Former Director, ICAR-Indian Institute of Soil Science, Bhopal, India

Md Mezbaul Bahar
CRC for Contamination Assessment and Remediation of the Environment (crc CARE), ATC Building, University of Newcastle, Callaghan, NSW, Australia; Global Centre for Environmental Remediation (GCER), University of Newcastle, University Drive, Callaghan, NSW, Australia

KK Bandyopadhyay
Division of Agricultural Physics, ICAR-Indian Agricultural Research Institute, New Delhi, India

Arlete Simões Barneze
Soil Biology Group, Wageningen University & Research, Wageningen, The Netherlands

Bartosz Bartkowski
Helmholtz Centre for Environmental Research – UFZ, Leipzig, Germany

Nicolas Beriot
Soil Physics and Land Management Group, Wageningen University & Research, Wageningen, The Netherlands

Bijay-Singh
Department of Soil Science, Punjab Agricultural University, Ludhiana, Punjab, India

Bhabananda Biswas
CRC for Contamination Assessment and Remediation of the Environment (crc CARE), ATC Building, University of Newcastle, Callaghan, NSW, Australia; Global Centre for Environmental Remediation (GCER), University of Newcastle, University Drive, Callaghan, NSW, Australia

Martin SA Blackwell
Net Zero and Resilient Farming, Rothamsted Research North Wyke, Okehampton, United Kingdom

Antra Boca
Latvia University of Life Sciences and Technologies, Jelgava, Latvia

Gerardo Bocco
Centro de Investigaciones en Geografía Ambiental, Universidad Nacional Autónoma de México, Mexico City, Mexico

Nanthi S Bolan
Global Centre for Environmental Remediation and International Centre for Balanced Land Use, University of Newcastle, Callaghan, NSW, Australia

Trond Børresen
Faculty of Environmental Sciences and Natural Resource Management, Norwegian University of Life Sciences, Ås, Norway

Eric C Brevik
College of Agricultural, Life, and Physical Sciences, Southern Illinois University, Carbondale, IL, United States

Christopher Brock
Forschungsring, Darmstadt, Germany

Laura Cardenas
Net Zero and Resilient Farming, Rothamsted Research North Wyke, Okehampton, United Kingdom

Elizabeth Chávez-García
Department of Geography, Faculty of Philosophy and Letters, National Autonomous University of Mexico, Mexico City, Mexico

Peter Clinton
New Zealand Forest Research Insititute Ltd (Trading as Scion Research), Rotorua, New Zealand

Joanna M Cloy
Carbon, Crop and Soils, Scotland's Rural College, Edinburgh, United Kingdom

Carlos E Cordova
Department of Geography, Oklahoma State University, Stillwater, OK, United States

Sophie Cornu

Aix Marseille University, CNRS, IRD, INRA, Coll France, CEREGE, Aix-en-Provence, France

Edoardo AC Costantini

CNR-IBE—Department of Biology, Agriculture and Food Sciences, Sesto Fiorentino, Florence, Italy

Lorna Anne Dawson

Centre for Forensic Soil Science, James Hutton Institute, Aberdeen, United Kingdom; Forensic Science, School of Pharmacy and Life Sciences, Robert Gordon University, Aberdeen, United Kingdom

Igor Costa de Freitas

Universidade Federal de Minas Gerais, Instituto de Ciências Agrárias, Montes Claros, Minas Gerais, Brazil

Seth Denizen

High Meadows Environmental Institute, Princeton, NJ, United States

Thomas Eichert

University of Applied Sciences Erfurt, Erfurt, Germany

Pierre Ellssel

Division of Organic Farming, University of Natural Resources and Life Sciences, Vienna, Austria

Norm Fausey

USDA Agricultural Research Service, Soil Drainage Research Unit, Columbus, OH, United States

Luiz Arnaldo Fernandes

Universidade Federal de Minas Gerais, Instituto de Ciências Agrárias, Montes Claros, Minas Gerais, Brazil

Victoria Fernández

Systems and Natural Resources Department, School of Forest Engineering, Universidad Politécnica de Madrid, Madrid, Spain

Eleonora Flores-Ramírez

Independent Researcher

Charles Andrew Francis

Kiesselbach Crops Research Laboratory, University of Nebraska–Lincoln, Lincoln, NE, United States

Uwe Franko

Halle, Germany

Leidivan Almeida Frazão

Universidade Federal de Minas Gerais, Instituto de Ciências Agrárias, Montes Claros, Minas Gerais, Brazil

Bernhard Freyer

Division of Organic Farming, University of Natural Resources and Life Sciences, Vienna, Austria

Jürgen K Friedel

Division of Organic Farming, University of Natural Resources and Life Sciences, Vienna, Austria

Harald Ginzky

German Environment Agency, Dessau-Roßlau, Germany

AM Gordon

CONTENTS OF ALL VOLUMES

VOLUME 1: SOIL BIOLOGY

Overview

Edaphology	1
<i>RM Goss and AL Ulery</i>	

Biodiversity	10
<i>Monica A Farfan and Diana H Wall</i>	

Soil organisms

Bacteriophage (Viruses)	16
<i>Li Bi, Ji-Zheng He, Dan-Ting Yu, Li-Li Han, and Hang-Wei Hu</i>	

Archaea	25
<i>Mikhail V Semenov</i>	

Bacteria	31
<i>Mikhail V Semenov</i>	

Soil protists	39
<i>Stefan Geisen, Nathalie Amacker, and Alexandre Jousset</i>	

Fungi including mycorrhizal fungi	49
<i>F Buscot</i>	

Soil algae	61
<i>Karen Baumann and Patrick Jung</i>	

Soil arthropods: Underfoot and all around	70
<i>Ernest C Bernard</i>	

Nematodes	105
<i>Deborah A Neher and Thomas O Powers</i>	

Earthworms: Essential ecosystem engineers providing vital ecosystem services	112
<i>Maria JI Briones</i>	

Complex structures

Soil biofilms: Evolving concepts and ecological functions	120
<i>Yichao Wu, Marc Redmile-Gordon, Peng Cai, Chunhui Gao, and Qiaoyun Huang</i>	

Biocrusts	127
<i>Matthew A Bowker, Jasmine Anenberg, Hilina Yohannes Kebede, Anita Antoninka, and Lydia Bailey</i>	

Functioning

Studying soil microbial communities: Culture-dependent approaches	139
<i>Eduardo K Mitter, Dasiel Obregon, Micaela Tosi, Heather Slinn, and Kari Dunfield</i>	

Studying soil microbial communities: Culture-independent approaches	146
<i>Tolulope Mafa-Attoye, Heather Slinn, Micaela Tosi, Evan Mayer, Dasiel Obregon, and Kari Dunfield</i>	

Studying microbial function in soil: Culture-independent techniques <i>Micaela Tosi, Dasiel Obregon, Heather Slinn, and Kari Dunfield</i>	155
Kinetics of microbial processes: General principles <i>NS Panikov</i>	168
Kinetics of microbial processes: Applications to soil biology <i>NS Panikov</i>	186
Biogeochemical cycles	
Carbon cycle in soils: Dynamics and management <i>Charles W Rice, Carlos B Pires, and Marcos VM Sarto</i>	219
Carbon storage in soils <i>Isabelle Basile-Doelsch, Tiphaine Chevallier, Marie-France Dignac, and Amandine Erktan</i>	228
Soil organic nitrogen <i>EJ Daly and KA Congreves</i>	243
Nitrification: Process, organisms and management <i>Jeanette M Norton and Yang Ouyang</i>	253
Microbial denitrification <i>Michael J Goss, Sergey Blagodatsky, and Adrian Unc</i>	261
Symbiotic nitrogen fixation <i>Florence Mus and Hsin-Hua Wu</i>	270
Nitrogen: Non-Symbiotic Nitrogen fixation in soils <i>Vadakattu VSR Gupta and Sarah S Roley</i>	283
Phosphorus in soils—Biological interactions <i>Nataliya Bilyera and Iryna Loginova</i>	293
Biological transformations of sulfur in soil <i>Chaoqun Wang and Maxim Dorodnikov</i>	303
Plant uptake of mineral nutrients <i>Angela Hodge</i>	310
Higher plants and their interactions with soil organisms	
Soil Biology: Root form and function <i>Magda Garbowski, Grégoire Freschet, Louise Jackson, Cynthia Brown, and Louise Comas</i>	321
Root mucilage: Chemistry and functions in soil <i>Yutong Jiang, Lijun Hou, Fang Ding, and Joann K Whalen</i>	332
Root exudates and microorganisms <i>Aidan De Sena, Krisztina Mosdossy, Joann K Whalen, and Chandra A Madramootoo</i>	343
Root interactions with the microbiome from the rhizoplane to the bulk soil: An overview <i>Joann K Whalen and Shamim Gul</i>	357
Microorganisms & biological processes	
Soil respiration <i>Jeremiah D Vallotton, Sergey Blagodatsky, and Adrian Unc</i>	369
Anaerobic soil processes <i>PW Inglett, D Said-Pullicino, and K Ramesh Reddy</i>	379
Mineral-organic-microbial interactions <i>Balwant Singh, Sabina Yeasmin, and Donald L Sparks</i>	387

Microbial ecology & management

Habitat for soil organisms and their functions <i>Alexandra Kravchenko and Andrey Guber</i>	407
Plant growth promoters <i>Elisa Gamalero, Gustavo Santoyo, and Bernard R Glick</i>	418
Inoculation with microorganisms <i>Maureen O'Callaghan and David Wright</i>	428
Biocontrol of soil-borne plant diseases <i>Mehrdad Mohammadiani and Matthew Bakker</i>	439
Management of soil biology for crop protection from biotic and abiotic stresses <i>Michael J Goss, Isabel Brito, and Mário Carvalho</i>	447
Trees, hedges, agroforestry and microbial diversity <i>Josiah B Judson, Joseph Holden, Pippa Chapman, and Marcelo Valadares Galdos</i>	469
Urban soil microbiome: Activity, diversity and functioning <i>Maria Korneykova, Ekaterina Kozlova, Kristina Ivashchenko, Maria Vasilieva, and Viacheslav Vasenev</i>	480
Microbiology of extreme soil environments <i>Patrice Dion</i>	494
Microbial mobility and transport in soils <i>Mohammad Reza Mosaddeghi, Adrian Unc, Ali Akbar Mahboubi, and Azadeh Safadoust</i>	512

Biology of soil amendments & contaminant degradation

Biology of compost <i>Heribert Insam, Thomas Klammersteiner, and María Gómez-Brandón</i>	522
Landfarming and its microbiology <i>Naga Raju Maddela, Balasubramanian Ramakrishnan, Kadiyala Venkateswarlu, and Mallavarapu Megharaj</i>	533
Biodegradation of organic contaminants <i>PB Hatzinger and JW Kelsey</i>	547
Biological aspects of manure management <i>Natasha Rayne and Bee Khim Chim</i>	558
Septic systems and municipal waste disposal on land <i>Charles P Gerba, Michael J Goss, and Adrian Unc</i>	567

Climate change

Climate change impacts on soil biology <i>Alberto Canarini, Lucia Fuchslueger, François-Xavier Joly, and Andreas Richter</i>	578
---	-----

VOLUME 2: CHEMISTRY**Basic Soil Chemistry**

Acidity and acidification <i>Siobhan Staunton</i>	1
pH <i>Siobhan Staunton</i>	8
Buffering capacity <i>Siobhan Staunton and Ravi Naidu</i>	15
Soil specific surface area <i>Emmanuel Arthur, Markus Tuller, and Kurt D Pennell</i>	22

Soil Analytical Chemistry

Cation exchange capacity and reactions <i>Donald S Ross and Ulf Skyllberg</i>	32
Testing for nutrients in the soil and the environment <i>Antonio P Mallarino</i>	43
Metal extraction and analysis <i>Guo Wang and Honghong Li</i>	50
Soil organic matter: Composition <i>Markus Kleber</i>	58
Physical fractionation techniques <i>Sam J Leuthold, Michelle L Haddix, Jocelyn Lavallee, and M Francesca Cotrufo</i>	68
The use of stable isotopes in soil science: Low atomic number elements <i>Chiara Pistocchi, Isabelle Bertrand, Kristýna Kantnerová, Astrid Oberson, Federica Tamburini, and Roland A Werner</i>	81
The use of radioactive isotopes to study soil pools and processes <i>Timothy I McLaren</i>	96
The use of stable isotopes in soil science: Metals <i>Cécile Quantin and Damien Guinoiseau</i>	107

Periodic Table

Alkali metals in soils <i>Guy J Levy and Asher Bar-Tal</i>	116
Alkaline earth metals in soil <i>Justin B Richardson</i>	126
Transition metals in soil <i>Siobhan Staunton</i>	135
Nitrogen and ammonia in soils <i>Nicholas T Girkin and Hannah V Cooper</i>	142
Phosphorus in soil <i>Luisella Celi, Maria Martin, and Elisabetta Barberis</i>	152
Aluminum in soils <i>Syuntaro Hiradate</i>	167
Iron in soils <i>Trolard Fabienne and Guilhem Bourrié</i>	176
Sulfur and selenium in soil <i>Dongli Liang, Fei Zhou, and Mingxing Qi</i>	192
Arsenic in soil <i>Md Imran Ullah Sarkar, Afsana Jahan, Md Tofail Hossain, Mohammad Mahmudur Rahman, and Ravi Naidu</i>	201
Non-transition elements: Metals and metalloids in soils <i>Natasha, Sana Khalid, Muhammad Shahid, Faiz Rabbani, and Camille Dumat</i>	214
Lanthanides, actinides and radon <i>Franco Ajmone Marsan and Mery Malandrino</i>	225
Halogens in soils <i>Svensson Teresia, Thiry Yves, Bueno Maïté, and Oelmann Yvonne</i>	234
Transformation of metals and metalloids by microorganisms <i>Susan M Glasauer, Euan P Burford, and Geoffrey Michael Gadd</i>	243
Dynamics of radionuclides <i>Siobhan Staunton</i>	256
Silicon and other non-metal elements from Group 14 <i>Bruno Delvaux and Zimin Li</i>	263

Soil Physical Chemistry

Chemical equilibria	274
<i>Arthur Paul Schwab</i>	
Dissolution and precipitation processes	284
<i>Zhenqing Shi, Shiwen Hu, Rong Li, and Yang Lu</i>	
Reactions, redox potential and kinetics	297
<i>Trolard Fabienne and Guilhem Bourrié</i>	
Sorption of organic chemicals in soil	315
<i>Joseph J Pignatello</i>	
Sorption—Oxyanions	327
<i>CP Schulthess, H Wijnja, W Yang, Anahita Khosravi, and Baoshan Xing</i>	
Sorption—Metals	336
<i>Daniel G Strawn and Donald L Sparks</i>	
Sorption–desorption kinetics	343
<i>Gautier Landrot and Donald L Sparks</i>	
Sorption-desorption hysteresis	355
<i>Wenhao Wu, Hongxia Zhu, and Kun Yang</i>	
Surface charge and zero-charge points	368
<i>J Chorover</i>	
Flocculation and dispersion	376
<i>Guy J Levy and Isaac Shainberg</i>	

Soil Carbon Chemistry

Soil organic matter dynamics	387
<i>Yu Luo and Jianming Xu</i>	
Soil proteins	396
<i>Siobhan Staunton</i>	
Biochar: Properties, mechanisms, and interactions in the soil	406
<i>Balwant Singh, Shamim Mia, and Marta Camps-Arbestain</i>	
Dissolved organic carbon	421
<i>Jason James and Rob Harrison</i>	
Black carbon, pyrogenic carbon	432
<i>Heike Knicker</i>	
Fire effects on soil	448
<i>Stefan H Doerr, Cristina Santín, and Jorge Mataix-Solera</i>	
Interfacial reactions of microorganisms with minerals and organic matter	458
<i>Rota Wagai, Puu-Tai Yang, and Klaus Kaiser</i>	
Pesticide fate in soils	470
<i>Pierre Benoit, Laure Mamy, Carole Bedos, and Enrique Barriuso</i>	
Soil organic matter in molecular simulations	483
<i>Martin H Gerzabek, Daniel Tunega, Edgar Galicia-Andrés, and Chris Oostenbrink</i>	

Soil Physical Analysis

Raman spectroscopy	497
<i>Anupam Das and Huiyuan Guo</i>	
Fourier transform infrared spectroscopic methods of soil analysis	510
<i>Derek Peak</i>	
Electron paramagnetic resonance spectroscopy: Part I Historic Perspectives	519

Abstract

In soils, the lithosphere, atmosphere, hydrosphere and biosphere overlap to form the pedosphere. Soils have the potential to benefit humans and the environment. The goods and services potentially rendered by soil are called soil potentials; the active services provided by a particular soil are soil functions. Soils with organisms living in them are considered ecosystems. Soils together with ecosystems play a regulating role in larger units like landscapes. Ecosystem services include people. The studies of soil ecology and ecosystem services were initiated in the 1970s. Among all types of degradation the biggest problem for soil protection worldwide seems to be soil erosion and the increase of settlements in fertile areas.

Glossary

Abiotic potentials Represent potential soil services, where the soils regulate the water regime, clean the air and provide technical raw materials.

Areal potentials Offer soil services for any type of use.

Biotic potentials Reflect potential soil services, where the soils are used as living space.

Ecosystem services Are the benefits people obtain from ecosystems.

Soil functions Are services, which soils under a specific land use carry out for humans and the environment.

Soil potentials Relate to services, which have the potential to benefit humans and the environment.

Introduction: The importance of soils in the environment and landscape

The soils on our planet are all useful. They provide the ecological balance, and primarily they allow plants and animals to thrive (Blume et al., 2016). Civilizations have used them for various purposes, which leads to the questions: How can a particular soil be used, or is this specific soil suitable for the required use?

These questions are as old as human interactions with soils. It started in the Younger Stone Age (Neolithic, began ~10,000 years ago), when people cleared forests to convert them into agricultural lands (Stahr et al., 2020). The earliest Greek and Roman approaches to soil classification were based on agricultural suitability.

In contrast, the beginning of modern Soil Science started with approaches to understand soil development. One of the founders of modern soil science, Dokuchaev (1883), observed soils across the Russian plateau and elaborated the dependence of soils (independent natural bodies) on soil forming factors, especially climate. Building on these ideas the most important soil philosopher, the Swiss Hans Jenny (Jenny, 1941), developed the central formula of soil formation:

$$\text{Soil} = f(t) (P, C, O, H, R)$$

P = parent material, rock or sediments, C = climate, O = organisms, plants and animals, H = humans, R = relief, t = time.

He later tried to quantify the efficiency of the individual factors over time (Jenny, 1980). Schlichting (1986) conceived rock and litter as the two factors that are transformed into soil, while the other factors (climate, relief, flora, fauna, humans) catalyze or regulate the course of transformation.

$$(\text{Rock} + \text{Litter}) \times \text{Time} \xrightarrow{\text{climate} \text{---} \text{relief} \text{---} \text{flora} \text{---} \text{fauna} \text{---} \text{humans}} \text{Soil}$$

These ideas increased the understanding of soil development, but diverted from the original idea to explain soil productivity and allocate land-use capabilities, which are delivered by our soils.

Meanwhile, the widely accepted approach is to describe and classify the soils according to their properties and genesis, where each particular site has its own influence, and therefore offers specific potentials and functions.

On the other hand, we have to find measures to evaluate the abilities of the same types of soil to provide goods and services, and to understand how to protect these from degradation. Soil classification and a soil suitability rating are two different approaches. The first tries to characterize a soil itself, while the other estimates the response of a soil to the demand of a certain land use. There is no soil suitable for all possible land uses; i.e. there is a specific soil suitability for growing rice (*Oryza sativa* L.), for grazing cattle, growing asparagus (*Asparagus officinalis* L.), or playing football.

Soils can be conceived as the skin of the Earth. The utmost importance of soil for the environment becomes clearly visible from this statement. The skin always protects the body within from extreme external influences. That means, it has a stabilizing influence on the water, air and temperature regimes. It buffers the extreme external changes in the atmosphere. It also covers most of the ground surface of the earth, including mountains, deserts and oceans (there are soils, which are covered with water all the year). Soil controls the vertical fluxes of air, water and energy. But soil properties at any one place differ widely from those at others according to the different combinations of soil forming factors. Therefore, the influence on the magnitude and direction of these processes will change from place to place. In landscapes we often find a regular catenary pattern of soils based on different landforms. These soils (soil landscapes) will affect the processes that occur in the landscape and provide support for infrastructure and cultural services.

Soil is a four-dimensional body

Soils have a carrying capacity. We use soils daily by standing, walking or driving on them. By doing so we see a two-dimensional section, i.e. a plane.

As soon as we acknowledge that plants penetrate the soil with their roots, or that water is infiltrating and being stored, we perceive the soil as a body. All types of soil potentials rely on the fact that solids, liquids and gases make up the soil body. The use of soils for plant production, energy exchange, water storage, biological and ecosystem processes requires a volume of soil to be effective. Therefore, a soil must be conceived of as a three-dimensional body at least.

Pushing with a spade into the garden soil at different times of the year allows us to realize that some properties change with time. The soil may be wet or dry, sticky, plastic or hard, light or dark colored, warm, cold or even frozen. All of these properties change reversibly with time. However, water percolating through the soil may dissolve substances and leach them irreversibly out of the soil and so change its properties over time. The same happens, when silty dust containing 'heavy' metals is eventually deposited and accumulates on top of the soil. Dead plant or animal residues will be transformed to soil organic matter (humus), and primary

Fig. 1 Relation between the pedosphere and the other spheres. Soil is in the overlap of the other spheres.

minerals into secondary minerals. Soils in general undergo irreversible changes. Extreme changes may occur, for example, if carbonate is leached in karstic areas over millions of years it can leave a deep acid clay rich soil. We can now realize that soils are four-dimensional objects.

“Soils are natural bodies and as such four-dimensional parts of the upper Earth crust. Herein rock (lithosphere), water (hydrosphere), air (atmosphere), and living organisms (biosphere) are interlinked” (Fig. 1).

Why soils matter?

Soils are a part of our environment and their protection should be mandatory as is the protection of all other environmental components (air, water and biota).

Soils are natural bodies

Soils as four dimensional bodies occur in the environment, which means in nature. In principal all soils can be formed under natural conditions and they are part of landscapes. Even anthropogenic soils find their place in the natural environment.

Like rare birds, precious orchids or plants we also have rare soils, which may occupy very little space in the pedosphere. They often have very specific functions in the soil cover such as allowing endemic plant species to grow or influencing different fluxes in a particular way. An example may be that they provide the precipitation of particular secondary minerals. The disappearance of such soils may change the water and energy balance significantly as well as the structure of the landscape. These soils need to be protected just as the protection of ecosystems is foreseen.

Soil processes often take a very long time to change the properties of the parent material or pre-existing soils significantly. Therefore, features that developed long ago are often still visible today in paleosols. For example, in Luvisols derived on loess, we find relicts of wooden poles from houses of the Younger Stone Age or flint knives in the ancient rubbish hollows or middens of the same people. Another example is the paleosols, which occur in the Sahara and that act as documents of earlier humid climates. Soils can be important archives of the Earth's history. Destruction of those soils is an irreversible loss of natural bodies and records of natural and cultural history.

Soils as archives of natural and cultural history

Soils are often laboratories of nature with a high productivity for example of reduction, oxidation or emission. This has to be protected. Likewise with precious crystals, we might observe soils and realize that they have admirable colors and structures. Therefore, it is important to preserve the natural beauty of such soils. It will be only a small proportion of soils, that we should protect because of their aesthetic and historical information. However, we should foresee these needs.

Soils are natural aesthetic objects' (Kubiena, 1946)

Furthermore, we can take into account that our soils as a whole deliver services in the regime of nature and specifically for the desires of human society. This is still the main reason why we have to protect the soil cover in order to be able to use its functions at any time. Yes, soils produce food and fodder and control environmental processes.

Potentials offered by soils

All soils are part of an environment. Our knowledge gathered during the last 200 years allows us to estimate the soil's potential much better as long as the soils are not heavily disturbed. A specific soil always has a function, e.g. it is used for growing potatoes.

At any time, the same soil has several types of potential. In accordance to its properties it may be used as a sports field, a footpath or a raw material for bricks. It may also have the potential to become a nature reserve, if different types of vegetation are present to provide habitats and food for birds and other animals. The potential goods and services a particular soil is able to provide should be visualized before making decisions on which function the soil should be used for.

If one asks, which principal possibilities soils have to serve for humans and in the environment, three groups of potential can be identified: These are the biotic potentials, abiotic potentials and areal potentials (Table 1).

The biotic potentials are related to the existence and growth of plants, animals and microorganisms, which need the soil as a living space to deliver food and energy. We may separate this potential in different groups, for example the production of food (wheat (*Triticum aestivum* L.), sugar cane (*Saccharum officinarum* L.), bananas (*Musa acuminata*), potatoes (*Solanum tuberosum* L.), rice (*O. sativa* L.), ...), the production of raw materials (timber, sisal fibers (*Agave sisalana* Perrine), cotton (*Gossypium hirsutum* L.), ...), the production of crops for energy (firewood, oil, ...), and the possibility to guarantee species survival. Many species have their seed bank in the soil, which means their reproduction is closely connected with the soil. Many microorganisms, which may be still unknown for example, can only be protected, provided that we give them the opportunity for reproduction in soils. The most important biotic potential is the one possibility for transformation. Here organic material as well as mineral materials existing in the soil or introduced into it can be altered and have a different appearance thereafter. Soils are exciting environmental laboratories. On the other hand, this potential is the transition between biotic and abiotic potentials because organic and mineral components can be transformed.

The abiotic potentials are those of gathering and filtering water, cleaning air and providing technical raw materials. Soils are a reservoir of water, and during periods, when the water balance is positive, they generate percolating water, which supplies groundwater and springs. In general, groundwater and spring water have drinking water quality. In Germany, the annual mean amount of water delivered is about 100 l per m² with a range from zero to more than a thousand. This range is also valid worldwide. Input of dust, gases or other elements that enter the soils can be filtered and fixed. Therefore, soils are also air and water filters. Finally, many soil components like stones, gravel, sand, clay, infusorial (diatomaceous) earth or lime may be useful raw materials for construction, to produce ceramics or fertilizers. Here soils act as sources of raw materials.

The areal potentials offer the place and space covered by each soil. Society generally honors these types of potential most. A parking place for a car is generally more expensive than the equivalent area for growing wheat, which could be produced on it. Such 'places to stand' may be offered to a person, a house, a factory or others. Important and increasing areas of land are used for transport. Furthermore, soils can be used as deposits for rubbish or construction materials and poisonous or toxic substances. Often places, where raw materials were first mined or extracted, become areas of waste deposits later that are then probably contaminated. The use of soils is also important for recreation. Recreation includes the admiration of nature, garden space, sports and playgrounds for children.

Table 1 Overview of all potentials that can serve ecology and society.

(1) Biotic potentials
a. Habitat for biota
b. Growth of food and feed crops
c. Growth of materials (e.g., cotton)
d. Growth of energy crops
e. Genetic resource
f. Transformation potential (the soil lab, also abiotic)
(2) Abiotic potentials
a. Air filter and regulator
b. Filter, buffer and supplier in the water cycle
c. Source of raw materials
(3) Areal potentials
a. Load and construction capacity
b. Traffic route
c. Deposit (landfill)
d. Recreation area

Fig. 2 Copulation of earthworms (*Lumbricus terrestris*) on the soil surface of a Vertic Cambisol.

If we want to differentiate between the quality of all types of potential, we realize that all biotic types can in principle be used reversibly. That means the use will maintain the potential. This accords with the transformation potential and also the abiotic potential of storing, infiltrating and delivering water and cleaning air, and it also applies to the recreation potential. On the other hand, extraction of raw materials and some uses of the areal potential will destroy other types of soil potential irreversibly. Utilization of types of reversible potential might also affect soil features that usually guarantee the potential to provide a particular service. However, the soils might have been used in such a way that the potential is destroyed or reduced over time.

Soil functions must be protected

Soils are habitats for organisms

The biosphere intersects with the pedosphere, therefore many organisms live in the soil. The dominant families here may be termites (Isoptera) and earthworms (Lumbricidae). In addition to these two groups manifold other macro-organisms need the soil as a habitat such as beetles, mice, moles, squirrels, gophers and so on (Dunger, 2008). They are responsible for forming and maintaining the soil's structure, which in turn is needed by plants and meso- and micro-fauna to grow successfully. The living conditions of these organisms need to be preserved in order to avoid their migration or even extinction.

Soils must be preserved as natural bodies. That means a certain minimum area is required to provide sustainable populations of soil organisms (Coleman and Crosley Jr, 1996). The aim is to preserve not only rare soils, but also the more regular, widespread soils under nature oriented conditions. Increasing the intensity of use may result in the loss of natural properties (Stahr et al., 2020) (Fig. 2).

Soils produce food and fodder

The production of food and fodder is extremely important for the maintenance of human life. Huge areas of soil are predominantly covered by pastures to feed a range of livestock such as sheep, goats, camels, horses and cattle. These natural pastures are in danger from overgrazing, and wind and water erosion. However, in intensive agriculture maize (*Zea mays* L.) or soybeans (*Glycine max* (L.) Merrill) are important food and fodder products. Crops need the soil as a rooting zone, for water supply, proper aeration, sustaining a particular temperature regime, providing nutrients and stabilizing the site. Food crops like maize, wheat (*T. aestivum* L.), barley (*Hordeum vulgare* L.), potatoes, sugar beet (*Beta vulgaris* L.), sugar cane and others make specific demands on the soil to succeed, which should be provided naturally or might need to be maintained by various agricultural practices. Worldwide, rice is a crop derived from floodplains that is cultivated in paddies, which need specific site characteristics and particular irrigation procedures to succeed. Many food crops that require specific conditions such as banana (*M. acuminata*), olives (*Olea europaea* L.), cacao (*Theobroma cacao* L. subsp. cacao), vine (*Vitis vinifera* L.), citrus (*Citrus* sp.), apples (*Malus domestica* Borkh.) and others are successfully cropped under a combination of soil and climate conditions. Sustainable agricultural practices must maintain soil structure, water and nutrient supply, and avoid toxic elements and soil erosion. When we want to use soils to reduce hunger from food insecurity, we should investigate its cause and potential health effects. The potential for food production often exists but there is often a lack of awareness of it. The increase in yields during the 20th century in many countries and crops demonstrates this; the 'green revolution' (Beek, 1978; McRae and Burnham, 1981).

However, a major problem worldwide is the loss of agricultural land to other uses like transport or settlement. The best soils are often in the neighborhood of growing big cities (consider Cairo, Egypt) (Fig. 3).

Fig. 3 Cows and Horses find their fodder in an alpine valley on Histosols and Histic Gleysols.

Soils produce raw materials

Natural raw materials can be produced in forests and agricultural fields, and have played an important role since humans settled on Earth. During the recent centuries of industrialization, it seemed that natural raw materials could be replaced increasingly by technical products. This tendency is now in reverse. Timber, cottonwood for paper, sisal fibers and other such products have gained greater importance again. Some of these crops can adapt to extreme conditions e.g. saline soils, very acid soils and steep slopes. This reduces the competition on more favorable sites to allow the production of food crops. Another benefit of the crops that provide raw materials is that their resistance against toxic substances is generally higher. Finally, the products produced from such a range of soils can be technically or naturally recycled. Therefore, this soil function will remain important, but must be brought into equilibrium with the demand for food by humankind.

The above situation could be solved by the co-cultivation of food and timber or other raw materials. On an agricultural field the production of cotton or wheat excludes the other, but there are other possibilities. There is the question: Does the production of mushrooms reduce timber production. In some situations the cultivation of one plant depends on another. For example, cocoa production needs shadow from other trees, but its production clearly needs space, which reduces timber growth. That means co-cultivation may be beneficial, but generally reduces the growth of one or both cultivars.

To maintain soil function, its natural fertility must be maintained, which may benefit from co-cultivation in some places. Fertility may be in danger through loss of nutrients, strong acidification or strong alkalinization. Under specific conditions monocultures, which are at environmental (soil chemical) limits can undergo continuous changes. This will result in unfavorable conditions for the continuation of the specific culture. The biggest problem seems to be the danger of soil erosion during or following harvest, when the crops are changed and the land may be left bare.

Soils support energy production

Rapeseed (*Brassica napus* L.) or firewood are crops grown for energy. However, assimilation by plants in general is a process which collects energy. Therefore, in principle, all soils on which plants grow are sites that store energy. However, in most cases the purpose of the growth is not the latter. In the case of plant material for firewood the use as fuel is clear (Kölling et al., 2007). To gain the energy back the plants may be burned, transformed into gasoline or into biogas.

In many cases the question as to whether the soil can support energy production is only answered after harvest. For example, maize can be grown as human food, as animal fodder and for biogas production. The order may even go in a sequence of the first being fodder with the following product, i.e. animal manure, used for biogas production. To maintain the above function, the stability of nutrient cycles and avoidance of soil erosion are again important considerations (Fig. 4).

Fig. 4 Rapeseed (*Brassica napus* L.) collects energy from soil (Rendzic Leptosol).

Soils are a genetic resource

All organisms need a specific environment in which to live and survive. Many organisms from microorganisms to vertebrates use soils as their habitat. Earthworms (Lumbricidae) and termites (Isoptera) are characteristic soil specific organisms.

The influence of the overall environment may induce genetic changes in soil biota. This is especially true for microorganisms. Therefore, we can expect that new microorganisms are created by the influence of the soil or that others are genetically altered through environmental conditions provided by internal soil properties. Many microorganisms remain to be identified in soils. Also new genetic varieties of macroorganisms may find opportune conditions for survival and multiplication.

Soils have a transformation potential

In soils nothing is really stable. Changes in conditions and properties can transform most substances that occur in soils. This may be the greatest potential and function that soils have. It can be a change in organic as well as mineral materials, and there can even be a transformation of the one form into the other. In general, these transformations generate organic substances from organic materials and minerals from minerals. However, mineral carbonates or nitrates may be formed from organic materials or mineral phosphates may be included in organic molecules.

There are many examples of the above: beech (*Fagus sylvatica* L.), maple (*Acer* L.) and oak (*Quercus* L.) leaves are transformed to humic substances; crystalline silicates are transformed to clay minerals, gibbsite or opal; iron will be released from rock minerals and precipitated in the form of different oxides; Sulfides can transform into sulfates under oxidizing conditions, but may be reduced again to other types of sulfides under reducing conditions. Even technical organic or inorganic products, which do not occur in nature, can be changed into natural products. This transformation function is at the border between biotic and abiotic functions.

Soils are air filters and regulators

External and internal soil surfaces can bind particles, which are dispersed in the air. Volatile gaseous molecules and ions can bind to soil surfaces. In general, the air quality over natural soils is better than that over sealed areas. In fact, vegetated soils in subhumid and humid areas are perfect air filters. On the contrary, deserted areas are sources of dust and locally even sand. Gases may also be emitted from volcanic areas that may acidify the soils around. Anthropogenic and specific agricultural desertification will often turn the filter into an emitter. Therefore, human activities should maintain the soil in conditions that can fix particles and gases. For example, aggregates on the soil surface should be stable, or surfaces should be kept vegetated and moist.

Soils accumulate particles to a large extent, for example loess or dune sands. Such additions may totally change the properties of the underlying soils, and they may be transformed into completely different soils.

Soils are a filter and buffer, and regulate the water cycle

All soils contain a liquid phase; this is an aqueous solution. Each soil has a pore volume, which can be filled with water or solution. Soils have a certain infiltration capacity. The water infiltrated may be stored or leave the soil and move into deeper rock pore systems. On the other hand, the water may evaporate or be taken up by plants. In humid periods water infiltrates the soil and is stored until the water retention capacity is reached. Amounts of water greater than the retention capacity may become seepage water.

Water flow is controlled by the gradient of the hydraulic or matric potential and the hydraulic conductivity. Therefore, depending on these regulating values water or the soil solution may move in any direction. Because gravity influences the hydraulic potential, vertical movement has priority, but the low hydraulic conductivity of certain subsoils or parent rocks causes an often dominant lateral water movement.

The important point is that the physical processes do not take place independently. The solution always reacts with the internal surface of the soil. It may exchange cations and anions with the internal surfaces; it may dissolve or precipitate salts and it may transport particles for some distance. Water, which has passed through soil and rock is often of drinking quality, which rainwater before entering the soil never was.

The water regulating filter and buffer capacity of soils must in general be seen as an advantage for the environment. This function has very different values for different types of soil. A soil may store between 1 and 400 L m⁻³ of water, and it may receive annually between 10 and more than 2000 L m⁻² of water. The hydraulic conductivity may change by up to a factor of a million times.

The different values that determine the importance of a soil in ecosystems are strongly related to soil fertility. Regulation of the water cycle is directly related to the natural soil condition. However, users must take care to maintain the benefits. Compaction, disturbance of pore connections, erosion and deposition can markedly alter the function of soils in the water cycle. However, there are also possibilities to improve structure and water exchange by appropriate activities. Land use must take care to maintain and improve the water regime.

Soils are a source of raw materials for technical processes

Soil materials can often be used as raw materials. Most widespread is the use of loams, which can be burned to make bricks. Other more specific and precious clays are used for ceramics such as porcelain or the widely used siliceous earth. Furthermore, lime as a basis for mortar or cement and also sand and gravel are used as construction materials. To extract these materials specific soils and sites must be found.

The fundamental difference between this function and all others mentioned above is that here the use destroys the potential as well as the soils. The materials used are altered in such a way that recycling is almost impossible. An exception are the clay bricks made by sun drying loam in dry and hot areas.

Soils cover a certain area

Soils have a load capacity

On most soils you may stand. By doing so, you use the areal function. You may also put other things like your car or your house on top of a soil. The two ways that you could use this potential are: 1. You may place something on a soil within the load bearing capacity and later take it away to put it elsewhere. 2. You construct something in or on top of a soil like a gas station or a sky scraper. The first is sustainable, the second destroys further use, especially other potentials for millennia.

Soils can be used for transport

You can ride your horse across grassland. This seems anarchic, but it is a principal function a soil may offer. Animals, humans and all types of vehicles may use the soil to move across. Nowadays, this function is regularly combined with the load function. First, a road or a highway is constructed, which seals the soil, and then different forms of transport may take place. We observe that worldwide roads cover an increasing part of the land. Therefore, it is of importance to construct them in such a way that allows later withdrawal. Most roads are repaired or reconstructed over a time scale of 20 years, but they are made as if it is for ever. Here engineers must learn to protect soils (Fig. 5).

Soils can take residues

In all agricultural, horticultural and forestry functions by-products or wastes occur. In this case the products, in principal, can be brought back to the fields directly as mulch or after stabilization by, for example, composting, in which a complete recycling should occur.

On the other hand, industrial or mining by-products cannot be returned to the environment from which they were released. In these case soils must take the residue load by deposition, which leads to complete alteration of the soil properties and their potential. In such cases toxicity often has to be taken into account. Also the change is long lasting, if not permanent. To control the situation all such effects should be minimized during operations. If the 'clean-up' of a site is required the surface soil should first be removed. The deposit should produce no leachates and at the end of the 'clean-up' process about three meters of uncontaminated soil material should be put on top to allow reintegration of sites into the landscape ecosystems (Fig. 6).

Soils are recreation areas

You may lay down on a soil just for fun and recreation. Visiting a mountain landscape, climbing a range of hills and enjoying the feeling or just the landscape view are also soil services for recreation. Walking or cycling along trails through an environmentally attractive reserve is again a good soil service. Sports are also taken for recreation. In all these cases the simple existence of soils in attractive landscapes is sufficient. However, this function is often combined with the use of the load capacity, where sportsgrounds are constructed or with the traffic function, where trails must be used. Therefore, in all those cases the environmental load must be minimized and reconstruction must be considered.

Fig. 5 Soils (Vertic Cambisol) are used for traffic while maize (*Zea mays* L.) is harvested.

The role of soils in ecosystems and landscapes

Soils are environmental filters and buffers

The pedosphere is an overlap between the lithosphere, hydrosphere, atmosphere and biosphere (Fig. 1). Soil pore systems allow contact between the different phases. The pore system also provides the opportunity for transport in gaseous, liquid and solid phases. Living organisms can also use the pore system or change the pores and soil structure to facilitate their existence. They may even change the pore system in favor of their demands.

During all these transport processes physical, chemical and biological contacts and reactions occur, where pollutants, nutrients and other elements can be adsorbed and desorbed until they reach equilibria. This is how soils function as buffers in the environment. The simplest case is the transport of particles of minerals or organic compounds, which reach soils through transport from outside the soil system (pedosphere). When they enter soils their movement velocity slows down or is stopped. They are thereby enriched in the soil and the soil itself is the filter.

Soils control the water regime

Soils have an eminent importance in the water regime of any landscape. The average water retention is permanently 1000 m³ per ha against gravity. The same amount of water can be stored in addition in the short term, but it will later become stagnant or leach out to groundwater or springs. During rain events water can infiltrate into soils provided the rate of infiltration is large enough. Otherwise the danger of erosion is considerable. Water retention provides the guarantee for plant water supply and its regulation.

Water has a regulation function in soils because it is mobile in all directions. The vertical downward transport starts with infiltration, leaching and drainage. The upward movement starts with capillary rise, plant uptake, transpiration and evaporation. Lateral water movement along a hydraulic gradient is also often important. All these transport processes not only carry water but also dissolved elements, ions and suspended solid particles.

One of the most exciting transport- and soil-forming processes is the illuviation of clay particles during strong rains in mildly acid soils. The transport of humic substances and aluminum is restricted to strongly acid and very humid conditions. Under the same conditions, and especially under reducing conditions, iron and manganese can be transported in any direction. The same can happen with lime (calcium carbonate) under neutral and mildly alkaline conditions. Finally, gypsum and soluble salts can be transported under neutral and alkaline pH mainly under semiarid conditions. Therefore, we can conclude that the water regime is a major controlling factor in the chemical environment of the soil together with pH and Eh (redox potential).

Soils support ecosystem services

Ecosystem services are the benefits people obtain from ecosystems (Fisher and Turner, 2008). That means there is a focus on relations to society and therefore they also have an economic perspective (Fisher et al., 2009). The services are separated in four ways. The 'regulating services' cover climate relevant facts like carbon sequestration, biological pest control, purification of water and air, and the enabling of natural pollination. The 'provisioning services' take food, feed and raw materials into account. Furthermore, they support genetic resources, medicinal resources, production of bio-minerals as well as energy supply. 'Supporting

Fig. 6 Waste deposit on the way to being reclaimed.

services' account for nutrient cycling and the provision of habitats. Finally, 'cultural services' cover landscape aesthetics, cultural heritage, outdoor recreation and more (Naidoo and Fisher, 2020).

All the services mentioned above are possible only through the influence of soils. As a matter of urgency, we have the duty to manage our soils in such a way that guarantees the maintenance of these services for present and future generations.

Water, air and soil: The basic environmental components

In the pedosphere we observe water, air and solids. Solids can occur as minerals and organic materials. However, the pedosphere is also interconnected with the atmosphere and hydrosphere. The interrelation between soil and air is related with the exchange of dust as well as of gases, and is of utmost importance (Blume et al., 2016; Amelung et al., 2018). These fluxes between the spheres may have significant influences. Emission of methane from peat (Histosols) will change the habitat significantly. Also iron, which is released in a spring, changes the water quality significantly and may produce ochreous precipitations.

In national and international legislation and laws we find that these basic environmental components are taken in the same sequence. Water is considered to be more important than air. Air is considered more important than soil. The reason is, that water and air are generally considered as common goods, but soils are generally a private good. The potentials of soils need to be socialized adequately to be considered in the legislation that is meant to protect them.

History of soil ecology

The knowledge of soils dates back to the first agricultural societies. In Mesopotamia, Egypt, India and China such knowledge was already recorded 10,000 years ago (Blume, 2003). In Central Europe it started 7000 years ago during the Neolithic Age. Greek literature started to document such knowledge (Plato) in about 400 BCE. Hildegard von Bingen (1150–1160) (2000) in the 12th century started to record the existing knowledge, which was mainly on topsoil. All this knowledge was focused on the agricultural use of soils. Soil science as a natural science is about 200 years old only. Famous people such as J.W. von Goethe, J. von Liebig, and A. Thaer were involved in this development. The first text book on soil science dates back to Sprengel (1837). In the 19th century the development of knowledge and understanding of soils occurred in North America (Hilgard), Germany (Fallou) and Russia (Dokuchaev). All this progress was almost entirely related to agriculture, forestry and geology (Blume, 2003; Blume, 2012).

The observations of Charles Darwin on the nature and behavior of earthworms (Lumbricidae) from 1840 to 1880 was the first document of biological processes in soils (Darwin, 1881).

In the first half of the 20th century systematic research on soil genesis and soil fertility resulted in the progress of soil classification, site evaluation and soil mapping (e.g. Schlichting, 1986). The development of land evaluation methods marks the peak of the practical outcome of traditional soil science (Storie, 1978; Sys et al., 1991). The modern soil classifications Soil Taxonomy (2014) and World Reference Base, WRB (2015) still order soils mainly for agricultural and silvicultural purposes.

Soil ecology became evident only one generation after the Second World War (Ehrlich and Ehrlich, 1970). Now soil regulations on climate, ecosystem functions and relations to humans play an important role (Fisher et al., 2009). However, the traditional functions like production of food and energy crops are increasingly dependent on the progress of soil ecology (Millennium Ecosystem Assessment (MEA), 2005; Naidoo and Fisher, 2020).

Conclusions and outlook

Soils can provide the potentials to serve people and landscapes in the future, but only if care is taken to maintain them. All soils accomplish certain functions and thereby they serve their owners and users in ecosystems and landscapes.

In addition to their primary functions (producing wheat and timber, regulating the water cycle and load capacity) soils provide ecosystem services (regulating, provisioning, supporting and cultural services).

Soils will continue to be important for humans, all wildlife and the environment in the future. Therefore, soil protection must be focused upon to ensure adequate maintenance of our soils and the ecosystem services that they provide for life now and for future generations.

Abstract

To feed 8 billion (B) people in 2022, agriculture occupies 37.1% of Earth's land. Yet, 15% (1.2 B) of population is undernourished and 25% (2 B) is malnourished. However, 30–40% of food produced globally is wasted. To feed 9.8 B by 2050, some argue for additional land, water, chemicals, and other inputs. In contrast, the soil-centric approach of producing more from less can spare 50% of the land and 66% of the water consumed in agriculture for conservation and rewilding of nature. Translating science into action to spare land for nature requires cooperation between land managers, researchers, policy makers and the private sector.

Key points

- Enough food is produced to feed the current and future population.
- A large amount of food produced is wasted.
- Hunger and malnutrition are man-made tragedies and are not due to lack of production.
- The approach of having additional land and inputs (water, fertilizers, energy) to feed the future population is inherently flawed.
- Of the 37% of land area and 70% of total water used for agriculture, adoption of a soil-centric approach of producing more from less can conserve land and water for nature.
- Rather than producing more calories, agriculture must be nutrition sensitive.
- Prudent governance must involve implementation of policies which are pro-nature, pro-soil, pro-farmer and pro-agriculture.
- Transformation of the world food systems by adoption of innovative farming systems can reconcile the need to provide adequate, safe, and nutritious food with the necessity of restoring the environment.
- Restoration of degraded soils (2 B ha) and deserted ecosystems can also sequester carbon in the terrestrial biosphere and limit global warming to below 2 °C.
- Choice of a healthy diet, and adoption of innovative farming systems can spare land for nature.

Introduction

World population has increased from about 1 billion (B) at the time of Malthus in circa 1800 to 8 B in 2022 and is projected to be 9.7 B by 2050 and 10.4 B by 2100 (U.N., 2022). The Green Revolution, the greatest success story in agriculture, increased global cereal production from 0.88 billion ton (B t) in 1960 to 3 B t in 2020 (by a factor of 3.3) when the population increased from 3.1 B to 7.7 B (by a factor of 2.5). Contrary to Malthus' prediction, the per capita cereal production increased by 32% from 284 kg to 375 kg. Indeed, the rate of food production being more than that of population growth averted global mass starvation.

The Green Revolution miracle was created by the intensification of agriculture on 5.2 B ha of land (1.5 B ha crop land and 3.7 B ha grazing or range land) through increased use of water, fertilizers, pesticides, and other energy-based materials applied to input-responsive and dwarf varieties.

Between 1961 and 2020 the increase in inputs was 11.6 times for N fertilizer, 4.4 times for P fertilizer, 3.2 times for K fertilizer, 5.2 times for pesticides, and 2.4 times in cropland area equipped for irrigation which increased from 144 M ha to 350 M ha.

The Green Revolution, however, was cereal centric (rice (*Oryza sativa* L.), wheat (*Triticum aestivum* L.)), based on heavy inputs of chemicals and irrigation, and focused on the intensification of monoculture. Thus, it caused environmental degradation, land desertification, decline in soil quality, eutrophication of water (i.e., algal bloom, hypoxia of coastal ecosystems), air pollution, and the emission of greenhouse gases (GHGs) into the atmosphere. One-third of the Earth's soils are degraded, depleted, and polluted (FAO/ITPS, 2015) and 30–35% of all anthropogenic emissions are contributed by global food systems (IPCC, 2018). In other words, agro-ecosystems are perceived to be responsible for the widespread problem of degraded soils, polluted waters, contaminated air, dwindling biodiversity, and denuded landscapes.

The present food systems are consuming a vast quantity of natural resources. For example, 38% of the Earth's surface is used for agriculture, 75% of agricultural land (3.7 B ha) is used for raising animals, 70% of the global fresh water withdrawn is used for irrigation, and 30–35% of global GHGs are emitted by agriculture. Yet, 1 in 7 persons (1.2 B out of 8 B people in 2022) are undernourished and 1 in 4 (2 B out of 8 B) are malnourished (FAO et al., 2022). The prevalence of undernutrition was estimated at 678 million (M) in the pre-COVID era of 2019, 782 M in 2020 and 828 M in 2021 because of the pandemic-induced disruptions in food production and supply chains. The number increased to 1200 M in 2022 because of the war in Ukraine and civil strife in other regions of the world.

Thus, business as usual cannot continue. There is a strong need for a paradigm shift in global food systems through the adoption of regenerative agricultural systems. Innovative agricultural systems must reconcile the need to meet the demands of a growing and increasingly affluent human population with the absolute necessity of improving the environment. Therefore, the objective of this chapter is to deliberate innovative farming systems, which make agriculture a solution for restoring the environment by producing more from less.

Feeding the world by 2050

Global food grain production of ~3B t in 2022 is enough to feed the present human population (8 B) and future population (9.7 B) by 2050. Thus, there is no need to expand agriculture, bring new land under agro-ecosystems by deforestation, and increase the use of fertilizers and pesticides to produce more food. This approach is counter-productive and is inherently flawed; both under-nutrition and malnutrition are man-made tragedies. The prevalence of under-nutrition is caused by social, economic, and political factors rather than by any shortfall in agricultural production. Similarly, prevalence of malnutrition or hidden hunger is caused by poor diet and food grown on degraded or polluted soils (Lal, 2009; Ewing-Chow, 2020), irrigation with contaminated water (Linderhof et al., 2021), and grown on soil mulched by polyethylene plastic (Madrid et al., 2022). Irrigation water can be a source of food-borne pathogens (Steele and Odumeru, 2004) and polluted irrigation water is making people unwell. Food grown in soil and water polluted by arsenic (As) is a major health hazard globally (Kayode et al., 2021; Sandhi et al., 2022). In addition, the effects on under nutrition of deficiency in micronutrients in soil (e.g., Zn, Mn, Fe), such as the role of selenium content in wheat on human health, are widely recognized (Tamás et al., 2010).

There is the problem of food waste which may be as much as 30–50% globally (van den Bos Verma et al., 2020), which must be effectively addressed. Improving access to food by addressing poverty, inequality, civil strife, and war is critically important as has been demonstrated by the war in Ukraine in 2022 and civil strife in Horn of Africa since 1990s. Food insecurity and hunger in rich countries is closely associated with inequalities (Pollard and Booth, 2019). Increasing the use of pulses (legumes (Fabaceae)) and promoting a plant-based diet can have a positive effect on human health and that of the planet (Lal, 2017).

Therefore, the Green Revolution 2.0 must be soil centric and based on soil resilience, eco-centric and based on eco-efficiency, and knowledge centric based on scientific innovations.

The overall strategy is to increase agronomic productivity from existing land, restore deserted land and degraded soils, enhance biological N fixation by legumes, protect prime soils against urbanization and non-agricultural uses, and spare land for nature. The aim is to produce more food from less land, less water, fewer inputs of fertilizer and pesticides, less use of energy, and less emission of GHGs.

Soil restorative farming system

One-third of Earth's surface is already degraded (FAO/ITPS, 2015). Predominant processes of soil degradation are erosion by water and wind, salinization, physical degradation of soil structure and attendant soil compaction or densification, acidification, and elemental imbalance (Oldeman, 1994). Severe depletion of soil organic carbon (SOC) stocks, through widespread use of extractive farming systems by resource-poor and small land holders of developing countries and indiscriminate and excessive use of inputs by largescale commercial farmers in developed economies, is a major factor aggravating anthropogenic emissions (Lal, 2004). Thus, there is a critical and urgent need for the adoption of soil-restorative farming systems.

Farming system refers to a mix of farming enterprises (i.e., crop, livestock, aquaculture, agroforestry, and fruit crops) to which a farm family allocates its resources (soil, water, landscape, biodiversity) to manage the existing environment effectively to attain the family goals (Lal and Miller, 1990). In addition to the biophysical approach, farming systems have also been defined with the focus on social and economic considerations, and emerging environmental consensus such as climate change (Lal, 2023). Because

of the strong interconnectivity of the numerous factors involved, there is also an increasing focus on the nexus approach to identifying appropriate farming systems for the site-specific situation (Lal, 2013), and for addressing the Sustainable Development Goals (SDGs) of Agenda 2030 of the United Nations (U.N., 2015). The rationale for the identification of innovative farming systems (Fig. 1) includes environmental, social, economic, cultural, and others. Because it is highly interactive, the nexus approach is appropriate.

Both the severity and extent of soil degradation and its adverse effects on numerous ecosystem services must be addressed at local, national, and global scales through the choice of site-specific farming systems. Further, goals for achieving high agronomic production to meet the demands of growing population must be reconciled with the even more urgent and critical goal of restoring the environment while maintaining an increasing trend in achieving per capita productivity (e.g., 32% gain in per capita cereal production between 1960 and 2020). Lal (1994) outlined several indices of sustainability, some of which are briefly outlined in Table 1.

Indices outlined in Table 1 can be assessed at different spatial and temporal scales. Spatial scale can be farm household, state, national or global level. Temporal scale is important to recognize in relation to the climate factor (C_t) which appears in indices 4, 5, and 6; it is relevant both now and in the future more than ever before.

In the context of saving land for nature, the following land-based factors are relevant (Lal, 1994):

$$L = \frac{C + F}{C}, \quad (1)$$

where L is the land-use factor or land-use intensity, C is the cropping period, and F is fallow period. In the modern concept of cover cropping, F is synonymous with the duration of cover cropping.

$$LER = \sum_{i=1}^n \left(\frac{Y_i}{Y_m} \right), \quad (2)$$

where LER is the land equivalent ratio where two crops (cereal and legume, or annual and perennial as in agroforestry) are grown on the same land at the same time, Y_i and Y_m are yield of component crops and n is the number of crop species grown on the same land. In scenarios where crop species may vary widely in their maturity period, an index called area time equivalent ratio (ATER) is used.

$$ATER = \frac{1}{t} \left[\sum_{i=1}^n \left(\frac{d * Y_i}{Y_m} \right) \right], \quad (3)$$

where d is the growing period of crop m in days and t is the time period in days for which the land remains occupied, or it is the growth period of the longest duration crop in the complex farming system.

The overall goal is to use these and other emerging indices to optimize resource use, produce more from less, and save land for nature.

Fig. 1 Identification of innovative farming systems to make agriculture a solution to environmental issues and return our spare land for nature.

Table 1 Some indices of assessing sustainability of farming systems.

Index	Formula	Variables
1. Productivity (P)	$P = \frac{p}{R}$	P = productivity p = total production R = resource used (N, water, energy, SOC, etc.)
2. Total factor productivity (TFP)	$TFP = \frac{p}{\sum_{i=1}^n (R_i \times C_i)}$	p = total production R = resource used C = cost of the resource n = number of resources used in achieving total production
3. Coefficient of sustainability (C_s)	$C_s = f(O_i, O_d, O_m)_t$	C_s = coefficient of sustainability O_i = output per unit input that maximizes per capita productivity or profit O_d = output per unit decline in the most limiting or non-renewable resource O_m = minimum assured output t = time
4. Index of sustainability (I_s)	$I_s = f(P_i * S_i * W_i * C_i)_t$	I_s = index of sustainability S_i = alteration in soil properties W_i = change in water resources and quality C_i = modification in climactic factor t = time
5. Agricultural sustainability (A_s)	$A_s = d(P_i * S_p * W_t * C_t)dt$	A_s = agricultural sustainability P_t = productivity per unit input of the limited or non-renewable resource S_p = critical soil property (SOM stock, rooting depth) W_t = available water capacity C_t = climactic factor t = time
6. Sustainability coefficient (S_c)	$S_c = f(P_i * P_d * P_m)_t$ $S_c = d(P_i * W_t * C_t)dt$	P_t = productivity per unit input of the limited or non-renewable resource P_d = productivity per unit decline in soil property P_m = minimum assured productivity S_c = critical level of soil property W_t = soil water regime and quality C_t = climactic factor t = time

Symp/on Sustainable Natural Resource Management for Sustainable Agriculture: Issues, Perspectives and Prospects in Semi-Arid Tropics, Vols 1 and 2, Indian Soil Agrom. New Delhi, India. A69–A89; Lal R (1994) *Methods and Guidelines for Assessing Sustainable Use of Soil and Water Resources in the Tropics*. Washington, D.C.: USDA/SMSS Bull. 21, 78.

Strategies for sparing land

Rather than deplete and degrade, innovative farming systems must be those which enhance and restore soil functions. Among the critical soil properties are SOC content, plant available water capacity (PAWC), rooting depth, soil pH, cation exchange capacity (CEC), water infiltration capacity, water stable aggregation and other indices (Kladivko et al., 2014). Choice of soil properties may vary and depend upon ecoregion, land use, farming system and other biophysical, socio-economic, and cultural conditions. Similarly, knowledge of the critical limits of these properties for optimal soil functions (i.e., SOC content of 2% by weight in the root zone) must be known for site-specific conditions. Thus, farming systems that degrade soil, which expand agriculture and take land from nature, are characterized by 5 Ds: deplete, degrade, destroy, discard, and dominate. These farming systems must be replaced by those which return land to nature by restoring and enhancing soil functions, and are characterized by 5 Rs: reduce, reuse, recycle, regenerate, and restore. Such a transformational change, based on a soil-centric strategy to return land to nature by translation of science into action, must be supported by prudent governance and appropriate policies (Lal, 2018a,b). Because agriculture must be a solution to environmental issues and farmers or land managers are the biggest stakeholders, policies must be pro-nature, pro-farmer, and pro-agriculture.

Nature-positive farming systems

Since the World Food System Summit (U.N., 2021), there has been a growing interest in regenerative agriculture (RA) and agro-ecology (AE) (Lal, 2020b, 2021a,b, 2022a,b). Regenerative agriculture is an approach to farming that uses soil conservation and restoration as the entry point to regenerate or restore natural resources, to strengthen essential ecosystem services and to reduce and minimize the harm done. Put simply, RA is nature-positive agriculture, and site-specific farming systems are adopted to

achieve these goals (Lal, 2020b). With soil health as an entry point it suggests the use of a farming system that replaces what is removed, wise or prudent response to what is changed, predict what may happen from anthropogenic and natural perturbations, and restore SOC content and stock by creating a positive soil–ecosystem organic carbon budget. Adoption of this strategy implies creating a positive (to replace the existing negative) SOC budget. Farming systems and RA practices that can create a positive SOC budget include conservation agriculture (CA) based on mulch farming together with complex rotations and integration of crops with trees and livestock (Lal, 2015, 2020a). These and other RA practices are inspired by eco-innovation, powered by non-carbon energy, driven by a circular economy and green infrastructure, and supported by the recarbonization of the terrestrial biosphere (Lal et al., 2012) as the bedrock of sustainable farming systems.

Despite its appeal and benefits, RA is a relatively new concept and a debatable issue. Because there is no one-size-fits-all and a range of practices can be listed as RA, there is a need for its precise definition, the criteria and methods for evaluation of its impact, and specific benefits to advancing SDGs of the U.N. Furthermore, standardization of RA is needed for site-specific situations. Under its overall umbrella, what is needed is the identification of key practices which include: nature positive multifunctional landscapes, prudent governance of these landscapes through relevant policies, plans to promote land system trends toward afforestation, intensification and upscaling of climate-resilient practices, urban agriculture based on soil-less culture practiced in dense cities, and education of the general public and policy makers in making a cultural value shift in favor of nature restoration (soil, vegetation, wetlands, biodiversity) and rewilding of land spared. In other words, RA must support nature conservation, restoration of deserted ecosystems and degraded soils, eco-intensification of high-productivity agricultural lands, and rewilding of marginal agricultural landscapes.

Agro-ecology

Similar to RA, the U.N. Food System Summit (U.N., 2021) also promoted the idea of ‘agro ecology’ (AE), as another innovation in food systems for restoration of the environment (Lal, 2022a). Rooted in the basic principles of ecology, AE is a multi-disciplinary and an integrative approach aimed at enhancing environmental friendliness of food systems, while also improving human health by implementing the “One Health” concept (Howard, 1940). The modern version of the “One Health” concept states that “health of soil, plants, animals, people, ecoregions and planetary processes is one and indivisible” (Lal, 2020d). It is often argued that AE is not based on science because it does not promote biotechnology and related innovations in addressing global issues (Lal, 2022a). That being the case, AE is not widely supported by the private sector. Nonetheless, basic principles of AE comprise: (i) enhancing use efficiency and reducing inputs, (ii) using cost-effective inputs through substitutions under site-specific conditions, (iii) integrating biodiversity in agroecosystems, (iv) improving connectivity of the consumer with producers, (v) identifying and using equitable farming systems, (vi) increasing community involvement in agroecosystems, and (vii) improving food security in urban centers (Lal, 2020e).

Enhancing acceptability of the AE concept implies the increased role of science so that it is relevant to global issues such as climate change, and other foci of SDGs. Acceptability of AE can be improved by embracing multiple dimensions of sustainability including environmental, social, economic, cultural, and institutional (Lal et al., 2016). It is therefore prudent to integrate the basic principles of AE with scientific innovations to address effectively poverty, hunger and malnutrition, and food safety while restoring degraded soils and the environment.

Rights-of-soil

The finite but ecologically fragile soil resource of the world, source of numerous ecosystem services essential to human wellbeing and nature conservancy, must be protected and managed prudently. The precious soil resource is shrinking both through degradation of its quality and functionality but also with conversion to non-agricultural uses (e.g., urbanization, industrialization, infrastructure, recreation, mining). An estimated 170,000 species of soil organisms have been identified (Wall and Moore, 1999; Wall et al., 2015) and is considered a living entity. Thus, similar to any other living entity, soil also must have the right to be protected against misuse and mismanagement so that it can also flourish and thrive (Lal, 2019, 2022b). Ethically, rights-of-soil are not based solely on its economic benefits but for protection of the planetary processes against pervasive and persistent impact of the Anthropocene and drastic perturbances of Earth’s life support systems. Similar, to other ecosystems (e.g., lakes, rivers, mountains, rain forest and nature on the whole), soil must have rights against deliberate activities that pollute, erode, deplete, degrade or decertify the precious resource and jeopardize its capacity to generate ecosystem services essential to all terrestrial life. Just and prudent use of soil through innovative land use and farming systems is neither immoral nor unethical, and also not illegal. It is in this context that emerging concepts of RA, AE, and other innovative ideas which enhance soil formations are not only pertinent but also essential to both human and all terrestrial life.

The concept of rights-of-soil is also pertinent to the idea of “Planetary Boundaries” (Rockström et al., 2009). The goal is to define planetary boundaries in which humanity can operate safely. Transgressing these boundaries can have disastrous consequences for humanity and the planet. Nine planetary boundaries identified by Rockström and colleagues are: climate change (CO₂ concentration of 350 ppm in the atmosphere), ocean acidification (mean surface sea water saturation state with respect to aragonite $\geq 80\%$ of pre-industrial level), biogeochemical N cycle (limit agricultural and industrial fixation of N₂ to 35 Tg N yr⁻¹),

and P cycle (annual P inflow to oceans not to exceed 10 times the natural background weathering of P), global freshwater use, and <15% ice-free land under cropland, among others. Thus, the concept of “rights-of-soil” can be used to limit the expansion of water for irrigation. It is a pertinent tool to keep humanity within the “Planetary Boundaries.”

Food system transformation

Food systems comprise inter-linked and value-added activities including growing, transporting, processing, distributing, using, preparing, consuming, and disposing of waste products from agriculture, fisheries, and forestry. Because of the widespread problem of under-nutrition and malnutrition, together with severe issues of soil and environmental degradation, and rapid global warming, the current food systems are not sustainable. The [FAO \(2018\)](#) defined a sustainable food system “That delivers food security and nutrition for all in such a way that the economic, social, or environmental bases to generate food security and nutrition for future generations are not compromised.” In accord with this definition, present food systems have several limitations that include: (i) inability to provide adequate nutrition, and a healthy and safe diet to the entire global population, (ii) susceptibility of food producing ecosystems to degrade soils, pollute waters, aggravate global warming, reduce biodiversity, and denude landscapes, (iii) vulnerability of food systems to emission of GHGs and aggravation of anthropogenic global warming, and (iv) failure to bridge the inequality gap among ‘haves and have nots’.

Thus, there is a strong need to develop and implement nature-positive food systems that eliminate hunger and malnutrition, and restore the environment. Therefore, nature-positive farming systems must: strengthen ecosystem services, minimize disservices, promote emission-negative farming, reduce input of chemicals, use bio-stimulants and organic amendments, promote a bio circular economy, support the “One-health” concept, use digital innovations, and re-carbonize the terrestrial biosphere.

Therefore, transformation of present food systems must be through the adoption of innovations which: (i) restore soil and biophysical environments, (ii) improve social equity and address human dimensions, (iii) promote prudent governance, (iv) identify and implement site-specific game changing solutions, (v) create local and national science-policy interfaces for sustainable food and farming systems. An important and much needed transformation would be that which leads to the adoption of nutrition sensitive agriculture (NSA). Malnutrition or hidden hunger is caused by lack of protein and deficiency of essential micronutrients in the diet. Therefore, NSA must focus on improving protein and micro-nutrients in the diet and decreasing consumption of fat. Apparently, healthy soil is the basic pre-requisite of NSA, because a healthy diet must come from food grown on healthy soil.

Therefore, strategies to combat hidden hunger are the restoration of soil health, complex crop rotation and farming systems based on the integration of crops with trees and livestock, dietary diversification with focus on pulses (legumes) and plant-based diet, and behavioral change through education and communication. An important part of the education is to promote the thesis that (i) healthy diet comes only from plants or animals grown on a healthy soil, (ii) when diet is poor medicine is of little use, and (iii) when diet is correct, medicine is needed less (ayurveda). Thus, there is a close inter-connectivity between innovative farming systems and a safe nutritious healthy diet.

Current and future aspirational land use

Most estimates of agricultural land use between 2020 and 2100 indicate expansion of cropland and of the area equipped for irrigation ([Table 2](#)). However, humanity cannot afford to take more land from nature because it is neither in the interest of the people nor of the planet. The prudent strategy is to reduce the land area under agriculture, spare land and rewild it to strengthen ecosystem services and minimize disservices.

An aspirational timetable of returning land to nature by adopting innovative farming systems is shown in [Table 3](#). By adopting the concept of producing more from less combined with the choice of a healthy diet and reduced food waste, it is possible to reduce the area under cropland to about 750 Mha or less (500 Mha) and pastureland to 1500 Mha or less (1000 Mha). However, with the adoption of drip sub-irrigation, the land area equipped for irrigation can be expanded to 500 Mha by 2100, and yet the water consumed may be reduced to one third of the present use for irrigation.

Farming systems for returning land to nature

Global food systems are in need of radical transformation through the choice of a healthy diet, and eco-intensification of agro-ecosystems designed to produce more from less, and education of the general public to reduce food waste which is estimated at 30 to 40% for grains and more for fresh vegetables and fruits. Innovative farming systems, based on the integration of crops with trees and livestock, and which involve regenerative agriculture and options to restore the soil and ecosystems, must be promoted so that half of the land currently under agriculture can be spared for nature by 2100. Sparing land for nature, rewilding of the terrestrial biosphere that has been drastically disturbed by anthropogenic activities, necessitates the restoration of deserted land and degraded soils through prudent governance and policies which are pro-nature. Growth of vegetation on returned land will sequester atmospheric CO₂ and mitigate anthropogenic global warming, enhance quality and renewability of natural waters and strengthen biodiversity. This would be a ‘win-win’ option for humans and nature.

Table 2 Past, present and future agricultural land use for agriculture (Mha).

Year (AD)	Population (M)	Cropland (M ha)	Pastureland (M ha)	Irrigated Land (M ha)
1	188	130	110	7
1800	989	420	510	8
2000	6896	1381	3357	260
2014	7200	1417	3516	331
2017	7550	1396	3369	335
2020	7600	1530	3406	399
2030	8600	1660		
2050	9800	1680		431
2100	11,200	1640

Abstract

Soil studies in archaeology are an essential component of archaeological research during survey and at excavation of sites, and for the interpretation of data. The application of methods and techniques developed in soil science have been adapted to solve archaeological problems. Geoarchaeology incorporates the methods and techniques of all geosciences in the field of archaeological research. Soil studies target several foci, including site formation and abandonment (site taphonomy), the reconstruction of ancient landscapes and environments, soils transformed by humans, including those transformed by ancient agricultural societies. This diversity of research encompasses studies at several scales, from those incorporating archaeological territories and landscapes to those at the microscopic level.

Key points

- Soils are an important part of archaeological research because of their connection to ancient environments and societies.
- Geoarchaeology acts as the connector between soil science and other earth science disciplines to archaeology.
- The effective application of soil science to archaeological research requires understanding of archaeological methods and the dynamics of ancient societies.
- Modern technology allows soils to be studied in archaeological contexts from microscopic to regional scales.

Introduction

Archaeology and soil science through geoarchaeology

Archaeology is the study of past societies through the analysis of physical remains left by humans. Such remains are often embedded in soils and sediments, for which soil science is an essential part in their history. In other cases, soils are considered important in archaeological research because they are essential resources for human societies, especially for those dedicated to farming. Furthermore, soils provide information about the environment and landscapes that humans inhabited in the past, which adds relevant information to the study of past societies.

Although the relation between soils and archaeology has existed for a long time, nowadays most soil research in archaeological projects develops under the umbrella of 'geoarchaeology'. Although geoarchaeology was originally defined as the application of earth science methods to archaeological research (Butzer, 1982), it has now developed into a multidisciplinary and interdisciplinary field that brings together specialists from the geosciences (e.g., geology, geography, geomorphology, and soil science) and archaeologists (Cordova, 2018). Nonetheless, the focus of geoarchaeology as a field linked to archaeological research implies that its specialists should be conversant in archaeological methods and theory.

In other words, a pedologist with no idea of archaeological matters might not be familiar with the problems archaeologists are trying to solve. It is one consideration in soil science to identify and interpret soil horizons, but another to establish a connection between the artifacts in the soil and the environmental context of the society that made them. Thus, to exemplify the proper involvement of soil research in archaeology, the following sections discuss methodological and practical cases of the involvement of soil specialists in geoarchaeological research.

How to read soil profiles in geoarchaeology?

Geoscience specialists often view stratigraphic profiles from the perspective of their own discipline. In other words, a geologist, soil scientist, and an archaeologist interpret the same stratigraphic section differently (Goldberg and MacPhail, 2006). However, under the lens of geoarchaeology those different views of the section can be brought together in an integrated view that is useful for reconstructing the evolution of a landscape associated with a particular or various ancient societies. To illustrate this point, the diagrams in Fig. 1 provide an example of a soil sequence at an archaeological site in central Mexico.

Fig. 1 View of a soil by an archaeologist, a pedologist, a geologist, and a ge archaeologist. Section extracted and modified from Cordova (2017). The locality represents a section exposed in a brickyard pit next to various archaeological sites of different ages.

Fig. 2 Different soil science methodological approaches and geoarchaeological research areas in the application of soil science used for archaeological research.

The first aspect to notice is the spatial context of the profile (top illustration in Fig. 1), which shows an exposed wall inside a brickyard pit near the town of Chicoloapan, Mexico. Its geomorphic context indicates that it is in a former floodplain of the Coatepec River; one can see the modern channel to the left of the diagram. Second, comes the archaeological context. To the left there is a promontory where the modern town of Chicoloapan is located. However, the town sits on a Late Aztec site (c. 1325–1521 CE), and in an area with substantial occupation in the Classic (c. 200–550 CE) and Epiclassic (550–900 CE) periods.

With the spatial and archaeological context in mind, one can proceed to interpret the profile under study. However, the interpretation varies depending on which specialist looks at the profile. Thus, a soil scientist, an archaeologist, and a geologist or geomorphologist would interpret it based on their specialties (middle of Fig. 2). Therefore, it is necessary to combine these three views (bottom of Fig. 1). Thus, the lesson learned here is that the interpretation of soil development is crucial for reconstructing ancient landscapes, but also it must be combined with the sedimentological and archaeological layers, while the geomorphic context (floodplain environment) and local spatial and archaeological contexts are considered. The resulting combined interpretation will help in the understanding of landscape change and use of the soil by the ancient inhabitants.

Methodological approaches

Soil research in geoarchaeology combines methods and approaches developed in pedology as well as those of other geosciences such as geomorphology, sedimentology, stratigraphy, geophysics, geochemistry, and petrology (Goldberg and MacPhail, 2006; Rapp Jr. and Hill, 2006). The methodological approaches involving soils, however, are diverse and depend on the focus of the archaeological research. To represent this relationship better, the diagram in Fig. 2 shows the foci of research inside an ellipse and the methodological approaches for each focus around it. In the following subsections the discussion centers on the archaeological research component and how soil science approaches participate in this using examples.

Soil formation processes in site taphonomy

In archaeology a ‘site’ (i.e., archaeological site) is “any place where there are physical remains of past human activities” (SAA, 2022). There are, however, various types of archaeological sites, each of which has its own association with the environment, and consequently with soils. Prehistoric sites often lack written records and range from merely camps where people settled temporarily to villages and even cities. In some instances, even a rock wall with rock paintings or petroglyphs is considered an archaeological site. In contrast, historic archaeological sites often have written records associated with them, and they can range from small units like a house or wall to complex settlements and built structures. This makes, for example, an abandoned factory anywhere in the world as much an archaeological site as an ancient Greek temple.

The association with soils varies depending on the site. For example, a prehistoric site would have more association with soil genesis than a site with structures of more recent age. A prehistoric site may comprise many thousands of years of accumulation such that it may be embedded in the soil formation itself. From a different perspective, the locality of an enclosure where cattle were kept underwent changes due to the incidence of animal feces and trampling, thus transforming the soil from the original state which may be found outside the enclosure. It is here where soil taphonomy enters with a soil methodological approach.

Site taphonomy refers to the study of transformation of a locality from its original condition through the many additions and destructions that occurred during its occupation, to the transformation after the site was abandoned. In the case of its transformation by humans, it includes materials added to the soil intentionally, including soil brought in from elsewhere, as well as the addition of inorganic and organic materials (e.g., sand, lime, and natural fertilizers) that change the physical and chemical properties of the soil.

Linked to soil taphonomy is the study of preservation of archaeological materials under different soil conditions (e.g., pH, carbonates, sand, expansive clays, organic content, etc.) (Goldberg and MacPhail, 2006). The techniques used in soil science that are applied to site taphonomy include soil micromorphology and many others such as X-ray diffraction used to determine the chemical and physical properties of soils (see Goldberg and MacPhail, 2006).

Soil as chronological control: Soil genesis, pedo-stratigraphic sequences and paleosols

Many times, inside and outside sites soil genesis and development becomes important as means of estimating time. In archaeology there are two main methods to determine age, the absolute and relative methods. The absolute method uses techniques to establish a numerical time frame, as in the case of radiocarbon dating. Relative methods use techniques to place soils within a reference time frame. However, by combining the two methodologies it is possible to provide a better time frame for the evolution of a landscape with more resolution (see next subsection).

To understand the role of soils as a means of chronological control one must consider that some soil orders or types have more developed structure (horizons), indicating that they have formed during long periods of time, while others are poorly developed, suggesting that they are young soils. This difference, however, may also be related to the prevalent climatic conditions (see next subsection).

Because climatic conditions are strongly linked to soil development, sequences of soils (i.e., pedo-stratigraphic sequences) provide a good way to correlate environmental change with known climatic conditions through time. This approach is more common at prehistoric archaeological sites belonging to the Lithic periods (e.g., Paleolithic, Mesolithic, and Neolithic), especially in open environments (e.g., outside caves and rock shelters).

The interpretive basis of a pedo-stratigraphic sequence is the alternation of sediments and soil horizons. The latter are often referred to as paleosols, which are soil horizons that are no longer soils because they are buried by younger sediments, such as alluvium (deposited by water), eolian (deposited by wind), or volcanic (buried by ashfall, pyroclastic flows) or simply buried under a lava flow. The importance of paleosols in archaeology is that in some cases people lived on these soils or farmed them. Thus, the artifacts, if diagnostic, provide relative ages to the paleosols. Conversely, radiocarbon dating from humic acids of the organic horizons of such paleosols can provide a numerical date for the artifacts.

Fig. 3 shows a sequence of soil horizons developed on redeposited loess and alluvium exposed on a terrace at the confluence of the Kama and Volga Rivers in Russia. In this case, the different soil horizons in the sequence attest to relatively warmer periods

Fig. 3 Pedo-stratigraphic sequence at Beganchik on a terrace at the confluence of the Kama and Volga rivers, Russia (Cordova et al., 2021). The picture shows the details of soil horizons indicated by the square on the main diagram.

(interstadials and interglacials), while loess accumulation and deformation by ice correspond colder periods (stadials and glacials). In the sequence one can see the modern soil (1) which is the Chernozem at the top of the sequence, which caps a sediment with Mesolithic occupations during a period about 14,000–12,000 years before the present. Farther below the sequence, an alluvial soil (2) includes hearths, artifacts, and fragments of bones, clearly indicating a prehistoric site. The idea of soil formation at this latitude (approximately 55° N) suggests that soil development and human occupation needed relatively warm temperatures. The relative position of the soil and fauna associated with it and its position below a layer of loess suggested that it belonged to the MIS 3 interstadial (approximately 60,000 to 27,000 years before the present). Radiocarbon dating of one of the hearths provided two ages around 48,000 years before the present, which places the soil exactly in the Krasnogorsk interstadial (or the Mooershoofd interstadial of Western Europe), a relatively warm period across most of Europe at the time (Cordova et al., 2021). In this part of Russia, the warm conditions permitted humans to pursue animals farther north than normal. This provides a clue that similar soil horizons in the region may be associated with this warm phase in the history of the last ice age.

The sequence has another paleosol that stands out by its thickness and darkness (3), which by correlation with other dated horizons across the Russian Plain corresponds to the so-called Mikulino paleosol, which relates to the penultimate interglacial, or MIS 5e (128,000–116,000 years before present). This interglacial had warm temperatures similar to the current ones, leading to the formation of soil like that of the modern Chernozems in the Russian Plains. Although there are remains of large fauna associated with this layer, there is no evidence of human occupation. Farther down towards the bottom of the sequence, there is another paleosol with gleyic characteristics (4), which may also correspond to an earlier warm period, but only absolute dating would be able to reveal its approximate age.

Soils in landscape evolution and paleoenvironmental reconstructions

The reconstruction of past landscapes and environments involves the use of soils as a measure of age and evolution of the landscape (the surface) and the environment (surrounding conditions) through time. These are aspects of geoarchaeological research that are crucial for understanding the survival and development of human societies in the past. This approach relates to geomorphology, the study of earth surface processes and landforms. The role of soil science in geomorphology is in terms of it both as a chronological method (previous subsection) and as an indicator of landscape stability (Holliday, 2004).

Landscape stability means no erosion and no accumulation, which allows plants to develop, eventually leading to pedogenesis. In contrast, periods of erosion and accumulation hinder soil development. Furthermore, stability of the landscape results under relatively wet, mild, and stable climatic conditions. Often these stable periods foster the presence of fauna and flora, thus becoming attractive to humans (Mandel, 2008). Accordingly, if conditions are unstable, sedimentation and erosion may impede the formation of soils. Put in the context of a floodplain environment, landscape instability results in frequent flooding, at times catastrophic, that may bury a soil or impede soil formation. In contrast, paucity of floods due to stable conditions, may allow soils to develop. The relation with archaeology is that stable landscapes are more likely to sustain human populations. However, if conditions change and sedimentation (flooding) occurs, the surface is abandoned, leaving behind an archaeological site.

The best example of a stable landscape appears in the paleosol S3 (see Fig. 1) in the sequence, which has archaeological material and even burials, suggesting permanent occupation. However, the site was abandoned as sedimentation buried the soil. Such an unstable period coincided with climatic instability and consequently social instability that occurred in the last three centuries of the first millennium AD in central Mexico (Cordova, 2017). The unstable conditions drove settlers elsewhere. Nonetheless, stable conditions returned a few centuries later.

Landscape instability is not unique to floodplain environments. Upland areas can also experience unstable periods due to surface erosion. However, like the floodplain counterpart, lack of erosion may lead to soil formation and the attraction of settlers, particularly farmers. The example shown in Fig. 4 provides an idea of widespread erosion of an upland landscape in the Texcoco region of central Mexico, where the remains of soil are found only on top of pedestal rock features (numbers 1–4 on Fig. 4a–b), indicating that at some point this was a stable landscape. Interestingly, the soils developed on the pedestals (Fig. 4c) suggest that soil formation was followed by farming, as the top horizon (Ap) contains evidence of the addition of materials for improving fertility (Cordova and Parsons, 1997). Interestingly, the stable period is not so far back in time; the archaeological materials associated with the farmed horizon correspond mainly to the Late Aztec period (AD 1325–1521), or even later. Further research has revealed that the widespread erosion occurred during a climatic and social crisis that took place in the 16th and 17th centuries (Cordova, 2017; Cordova and Parsons, 1997).

Studies of soil and landscape stability may encompass periods in the order of millennia where stability does not necessarily relate to farming or demographic pressures, but periods of climatic instability. This is the case for numerous examples across the Great Plains of North America in prehistoric times (Mandel, 2008; Holliday, 2004).

Soils as an agricultural resource: Farmed soils and anthrosols

Farmed soils, and particularly those that are completely artificial are related to soil taphonomy, and landscape and environmental stability. A farmed soil is often a natural soil horizon that has been plowed, and which often has the designation Ap. The farmed horizon may have physical and chemical characteristics that suggest the addition of manure and perhaps soil from elsewhere, but in general the altered horizon would have continuity with the original subjacent soil (similar to the example in Fig. 4c). There are also cases of farmed soils with the so called 'agric' horizon, or the horizon below the plow horizon that has accumulated clay, silt and

Fig. 4 Eroded landscapes with pedestal rocks capped by a relict soil which here is used to reconstruct the pre-erosional topography of the site. The soil on the pedestal has signs of being farmed and contains archaeological material bearing a date of c. 16th century as the maximum age of the erosion. (A) Simplified topographic profile of the study area; numbers are used as reference points. (B) Photograph of the study area with reference points; (C) Soil profile from the pedestal marked as point 2; (D) Archaeological material recovered from the bottom of the Ap horizon.

humus leached from above, often suggesting the implementation of irrigation (Bockheim, 2014). In this, and many other cases, soil horizons present evidence of agricultural management in the past, an aspect that is of great interest in archaeological research (Homburg and Sandor, 2011).

In some cases, distinguishing a farmed soil from non-farmed soils may not be easy. There are cases, for example, in which soil horizons bear signatures of farming. One case is the use of stable carbon isotopes in soils under the dense tropical vegetation of the Mayan region (Fig. 5). During the Classic Maya period (roughly AD 250–900) population in the lowlands of northern Guatemala and Belize, and Mexico’s Yucatan Peninsula grew to the point that broad areas of tropical rainforest were removed, and their soils farmed by the slash-and-burn technique. In some cases, the evidence of this process is clear either because of the ash layers or artificial soils (e.g., anthrosols), whereas in others it is more difficult to observe in the field. This is the case of the soil profiles in Fig. 5 in which the Ab horizons present a shift in $\delta^{13}\text{C}$ towards the C_4 plants, often grasses and maize, *Zea mays* L. (C_4 plant) (Beach et al., 2018). Non-farmed soils retain the low signature of C_3 plants. This is the case for those horizons above and below Ab, which sustained trees (typical C_3 plants). Thus, the Ab horizon with the C_4 plant signature is an isotopic marker of the Classic period.

Fig. 5 Selection of soil profiles in the Maya lowlands, displaying $\delta^{13}\text{C}$ through their horizons. Adapted from Beach T, Ulmer A, Cook D, Brennan ML, Luzzadder-Beach S, Doyle C, Eshleman S, Krause S, Cortes-Rincon M and Terry R (2018) Geoarchaeology and tropical forest soil catenas of northwestern Belize. *Quaternary International* 463: 198–217.

Farmed soils can also be entirely artificial soils, in which case they are referred to as ‘anthrosols’ because their formation depends entirely on human activities. In this case an anthrosol is a result of the deliberate accumulation of materials, or in some cases of the indirect accumulation of materials, that create a surface where plants can grow. The study of anthrosols in archaeology varies around the world, depending on the geomorphic, biogeographic, and climatic context. One of the most studied soils in recent times is the so called ‘dark’ or ‘black earths’. The term may be used indiscriminately for examples of dark soils or those of anthropic origin in different parts of the world. Dark earths (also known as ‘terra preta’) are soils developed with the accumulation of burned and slashed materials by ancient farmers in the Amazon region (Kern et al., 2004). They are visually distinctive from the typical Oxisols developed under a wet tropical climate. Similar soils have also been reported in the Mayan region, often in contexts where terracing involved the creation of soils, and where the dark soils are distinctive from the pale or light color of limestone derived soils (Beach et al., 2018). The European black earths, on the other hand are soils that are often typical of archaeological contexts in urban areas. Their origin is often debated, although in many cases they have resulted from the ruralization of urban or peri-urban areas in the Middle Ages (Nicosia and Devos, 2014). Their formation is often associated with the accumulation of manure or with artificially induced pastures, although this varies in many places suggesting that these soils may also have had multiple origins and formed under different socioeconomic circumstances (Nicosia and Devos, 2014).

Scales of research and techniques

Soils in geoarchaeology can be studied at different spatial scales. Thus, one can study soils across large areas especially when soil characteristics vary across the landscape, while at the same time looking at the properties of those soils inside and outside sites in more detail (Table 1). The scale used in soil research in geoarchaeology also depends on the stage of the archaeological process under study (e.g., survey, excavation, and analysis). In general, soil studies in survey will require involvement at macro- and meso-scales, whereas those involved in excavation are likely to focus on micro spatial scales. The methods and techniques developed in soil science at each scale are used in archaeological research at the different phases, namely survey, excavation, and laboratory research (right column in Table 1).

Table 1 Different scales of research and their associated methodological approaches and application in the archaeological process.

Scale	Methodological approach	Stage in the archaeological research process
Macroscale	Mapping, remote sensing, GIS, stratigraphic correlation, spatial analysis	Survey, analysis
Mesoscale	Pedostratigraphic profiles, geochemistry, macrofossils.	Survey, excavation, analysis
Microscale	Micromorphology, trace elements, microfossils, geochemistry	Excavation, analysis

At the macroscale, archaeological research involves mainly survey, though in geoarchaeology there might be research associated with the search for evidence of environmental change (including climatic change) and landscape change. Thus, at this stage soil mapping becomes an important part of the research, which is often aided by geographic information systems (GIS). Additionally, archaeological research uses remote sensing techniques especially to look for irregularities on the ground represented by differences in vegetation and soils that may indicate previous anthropogenic developments. Such large scale investigation then often leads to mesoscale research associated with excavation at certain sites. It is in this part of the process where soil science may contribute to studying landscape stability/instability and environmental change.

At the mesoscale, soil methodologies and techniques are often applied to smaller areas. In this case, it may involve survey of a small area of a site or a full site. This could still be part of the survey phase, but also of excavation. It may also involve the use of geophysical tools to provide data that are sometimes used to search for areas of occupation below the subsoil. Test pits (1 m × 1 m) are often dug to expose sediments and soils, which may be followed by field sampling of the profile and laboratory analyses. Samples may be taken preserving the natural soil aggregation to make slides for micromorphological investigations. The sampling phase might also involve examining exposures of soils outside settlement sites, especially in areas of accumulation like floodplains. Techniques used here may involve quick analyses of physical and chemical properties of the soil, especially to study soil development or indicators of human transformation of the soil in the past.

At the microscale the main tasks are detailed excavations of sites, and it is here where soil science contributes more to the aspect of soil taphonomy. Techniques used here mainly involve soil micromorphology and certain chemical analyses. Outside archaeological sites, microscale studies may target anthrosols and farmed soils, for which soil micromorphology would provide valuable information about the materials they are made of, or as in the case of the profiles in Fig. 5, would provide information on the processes of farming. Micromorphology would also provide information on soil processes induced by humans such as clay translocation, salinization, and so on.

Final remarks

Soil research is an integral part of archaeological research, which is now developing in tandem with geology, geomorphology and other geosciences under the broad field of geoarchaeology. Soil studies are an essential part of the archaeological research during survey, excavation, and laboratory analysis.

Among the many contributions of soil research to archaeology, one can cite the following:

- The process of abandonment and degradation of archaeological sites and their artifacts
- Source of absolute and relative dates for stratigraphic sequences
- Survey of archaeological sites
- Physical and chemical properties of soils inside and outside archaeological site
- Climatic and environmental changes as well as stability of the landscape
- Reconstruction of past ecosystems
- Soils as an agricultural resource
- Details on past agricultural practices

The study of soils in geoarchaeological research encompass various spatial scales. The macroscale involves regional survey of soils and their association with ancient settlements for which a series of mapping techniques are implemented. This also involves the study of soils as a measure of landscape stability and environmental change. At the mesoscale soil research includes the inspection of sites and the transformation of soils by human activities, which normally comprises studies of the physical and chemical properties of soils. Finally, at the microscale, soil properties of certain layers or horizons are examined, often associated with site taphonomy, but also with farmed and anthropogenic soils.

In conclusion, it is possible to see that methods and techniques used in soil science have been adapted to archaeological research via the broad research approach known as geoarchaeology. This means, however, that soil scientists dedicated to this field should be conversant with the theoretical and methodological approaches in other geosciences and archaeology.

Abstract

Civilization is tied to soil through our reliance on agriculture and building materials. As early civilizations developed new agricultural strategies, their knowledge of soil also expanded. Major innovations included irrigation, terracing, use of plows, contour tillage, soil classification, and maintaining soil fertility through intercropping, crop rotations, fallowing, and amendments like manure and ash to develop sustainable agricultural systems. In several noteworthy cases, soil degradation contributed to civilization collapse. In addition, soils are influenced by and influence the global climate system. Changing climates have contributed to past civilization collapses, and societies that rely on degraded soils are less resilient and adaptable to climate change.

Key points

- Describe major agricultural soils and systems for ancient civilizations of the world
- Review examples of agricultural soil management, sustainability, resilience, and degradation in the context of climate change in the past
- Demonstrate the relevance of soil–agriculture–climate change interactions for past civilizations in modeling and adapting to climate change in the future

Introduction

The success of modern and ancient societies is inextricably linked to the availability and distribution of productive, well-watered soils and landforms suitable for agriculture. Ancient agricultural systems permitted cultures to obtain more food and store it for longer periods, which in turn supported permanent settlements and growing populations beyond that possible by hunting and gathering. Agriculture is tied to soil that functions as the medium for anchoring plants and supplying water and nutrients to crops. Human knowledge of soil must have evolved since the earliest days of agriculture, but it is noteworthy Neolithic settlements were located near rich soils that were well-suited to support agriculture. This indicates that these ancient farmers already had relatively sophisticated knowledge about soil fertility and productivity (Montgomery, 2007). As early civilizations rapidly developed new agricultural strategies, their knowledge and management of soil also expanded. Major innovations in the first few millennia of agriculture included irrigation, terracing, plows, contour tillage, and soil classification. Soil fertility was maintained by intercropping, crop rotations that included legumes, fallowing, manuring, and the addition of ash to develop sustainable agricultural systems that persisted for millennia. By contrast, poor agricultural management has caused soil degradation that contributed to civilization collapse. Changing climates have also contributed to such collapse in the past, with societies coping with degraded soils that were more susceptible to problems caused by climate change. It is important to understand soil–climate–human interactions. Gaining a holistic understanding transcends any single academic field. Interdisciplinary and transdisciplinary studies that integrate the expertise of soil scientists, agronomists, climatologists, archeologists, and various physical, biological, and social scientists are necessary to plan better for climate change and how to manage it. Climate change and its impact on both soils and civilizations is a major topic of interest today as a way to adapt to changes in climate in the future.

Soil management in early civilizations

Many early civilizations developed ways to improve agricultural production, and much of our understanding of early soil knowledge is from archeological studies (Brevik et al., 2018) (Fig. 1). The earliest evidence of soil manipulation for agricultural production dates to approximately 9000 BCE; between 7500 and 500 BCE major innovations included irrigation terracing, early plows, and contour tillage (Troeh et al., 2004). Observations of natural plant growth, soil colors and textures, well-watered landscape positions, and trial and error were ways that early people selected the best land for farming. Soil spatial patterns were recognized by different civilizations to select cropping (Krupenikov, 1992) and settlement sites by 3000–2000 BCE. Early Chinese (Gong et al., 2003) and Greek civilizations (Krupenikov, 1992) were classifying soils by 300 BCE. The study of soils had not yet advanced to a science in early civilizations, but ancient cultures were well aware of the importance of soils and how to manipulate them to their advantage. Krupenikov (1992) argues that soil science appeared as an empirical field about 500–0 BCE. Examples of early knowledge from different parts of the world are reviewed below.

Asia and Oceania

The oldest indications of human management of soil found to date come from Asia, near Jarmo in Iraq, and date to about 9000 BCE (Troeh et al., 2004) and shortly afterwards in Abu Hureyra in modern Syria (Montgomery, 2007). Irrigation was developed in modern-day Iraq by 7500 BCE (Troeh et al., 2004), and early plows were developed in the Middle East between 6000 and 4000 BCE, which revolutionized soil preparation for planting (Hillel, 1991). The first cultivation and plow appeared about the same time in fertile land in Mesopotamia, but it was necessary to increase crop production by means other than just adding new agricultural fields (Montgomery, 2007). Sheep and goats were domesticated by about 8000 BCE in the Zagros Mountains area and manure was used to fertilize fields (Montgomery, 2007). Furthermore, fields were created from 'artificial' soils that formed small islands in marshes as early as 3000 BCE (Fitzpatrick, 2004). Terraces were first used in the Near East around 4000–3000 BCE. Agricultural production began in China not long after it began in the Middle East (Montgomery, 2007), with rice (*Oryza sativa* L.) cultivated by 7000 BCE, paddy soils used by 4000 BCE (Cao et al., 2006), and terraces by 1000 BCE. Plowing was a common practice in India by 3000 BCE and farmers amended soils in Uzbekistan to improve both fertility and texture as early as 2000 BCE (Krupenikov, 1992). Early drainage canals found in Papua New Guinea date to 7000 BCE with more extensive drainage systems and the construction of raised soil beds by 4000 BCE (Vasey, 2002).

Europe

Agriculture spread from the Middle East west into Europe, starting with Turkey and Greece about 6300 BCE (Montgomery, 2007). Ancient Greek philosopher-scientists recognized differences between soils by the second millennium BCE; they are credited with the first recorded works that show knowledge of soil properties and with developing the concept of a soil profile (Krupenikov, 1992). They understood that plant nutrients were supplied by the soil and wrote of water storage in soils (Hillel, 1991).

Their attention to soils allowed the Greeks to match crops to the best locations for production (Krupenikov, 1992). Despite this, soil erosion and degradation became major problems in ancient Greece.

Romans utilized manure and green manure to enhance soil fertility, built terraces to reduce erosion (Troeh et al., 2004), classified soils, and developed soil fertility tests. Because the Roman Empire encircled the Mediterranean and reached far into western and northern Europe (see Fig. 1), Roman ideas on soils and agriculture were widespread. In other parts of Europe, contour tillage was developed in the British Isles prior to the Roman conquest, and some cultivated land on steep slopes was reforested for conservation purposes by 900 CE (Krupenikov, 1992).

Africa

North Africa had some very successful ancient agricultural societies. The ancient Egyptian civilization lasted for 3000 years, from 3300 BCE to 332 BCE, based on agriculture sustained by frequent flooding of the Nile River that restored fertility by depositing organic-rich sediments. Farther west, Carthage became a political power around 600 BCE based on the cultivation of cereals, fruits, vegetables, and nuts. The Roman conquest of Carthage in 146 BCE secured land for crops needed to feed Rome, and the Romans were very interested to learn of Mago's handbook of Carthaginian agriculture (Montgomery, 2007). The Carthaginians had advanced cultivation and irrigation systems, but wind and water erosion eventually removed enough topsoil around Carthage to make agriculture unsustainable.

Americas

The earliest evidence of agriculture in the Americas dates to between 8500 and 7000 BCE in Peru and Mexico (Vasey, 2002). Maize (*Zea mays* L.) was domesticated by 7000 BCE, which led small dispersed villages in Mesoamerica to grow into larger towns that served as cultural and economic centers (Montgomery, 2007). Mayan civilization thrived in Central America from about 600 BCE until 800–900 CE as population increased from around 200,000 to 3–6 million, supported by dynamic and ever evolving agricultural systems that varied spatially and temporally (Dunning et al., 2012). Population grew as agriculture was intensified. Mayan agriculture evolved from slash and burn under low population density to raised fields, drainage by canals in lowlands, and extensive terraces on slopes, but they lacked domesticated animals and manure for renewing soil fertility.

Crops were first cultivated by Native Americans in the Midwest and Eastern USA by 5000 BCE. Intercropping, ash amendments, and fallowing rejuvenated soil fertility. Agricultural management in the American Southwest included runoff terraces, rock mulch, and irrigation systems matched to particular soils and landforms (Homburg and Sandor, 2011). Domesticated maize spread from Mexico's Tehuacan Valley north to the American Southwest by 2000 BCE.

Agricultural terraces date back at least 4000 years in Peru, and many ancient terraces are still cultivated today (Denevan, 2001; Sandor and Homburg, 2017). Intercropping, crop rotations that included legumes, fallowing, and ash were used to maintain soil fertility. Animal domestication in South America provided manure that was absent elsewhere in the Americas. Native Americans in the Bolivian Amazon established raised fields and canal systems that supported complex societies with a relatively high population density (Lombardo et al., 2015).

In the Amazon Basin, human activities created patches of Dark Earth, or terra preta, between 500 BCE and 1640 CE. Terra preta have thickened A horizons formed from surficial accumulation of archeological residues at ancient settlements and associated agricultural fields and gardens. These residues include charcoal, ash, organic refuse, fragments of pottery, and stone, bone, and shell artifacts. Most tropical soils are marginal for agriculture due to intensive chemical weathering, but terra preta have high fertility resulting from elevated soil organic matter, pH, cation exchange capacity, nutrients (especially phosphorus (P), calcium (Ca), magnesium (Mg), zinc (Zn), and manganese (Mn)), and favorable physical properties, including greater workability, permeability, water-holding capacity, aggregate stability, and root penetrability. It is unknown if terra preta were initially created incidentally or intentionally, but over time these fertile soils were managed deliberately for agriculture (Lombardo et al., 2021). Crop productivity is significantly increased in terra preta relative to neighboring areas where highly weathered and leached, acidic Oxisols and Ultisols typify tropical environments. Recalcitrant, pyrogenic carbon from charcoal and stable humus account for much of their fertility. The sustainability, food security, and environmental benefits of terra preta are recognized today. They sequester substantial amounts of carbon, which has spurred research over the last two decades on the properties and benefits of biochar (charcoal produced by pyrolysis of biomass in an oxygen-limited environment for uses other than as fuel) as a soil amendment and many other purposes. Biochar has become a leading candidate for both mitigating climate change and boosting agricultural productivity sustainably.

Effects of ancient agriculture on soils and societies

Humans have manipulated soils for at least 11,000 years to improve agricultural production. A common result was soil degradation (Richter, 2007). Water and wind erosion are natural geologic processes, but agriculture is known to accelerate erosion and strip away topsoil faster than it can form in many environments. On a worldwide basis, rill, gully, and sheetwash erosion remains the dominant cause of soil degradation. Compaction, nutrient loss, and salinization are also major causes of soil degradation. Table 1 summarizes the main physical and chemical properties used for assessing soil degradation. There are also numerous examples of sustainable systems. We can learn from both sustainable and unsustainable practices in the past. This section provides examples of both sustainability and soil degradation severe enough to have caused or contributed significantly to civilization decline.

Table 1 Soil properties that may indicate soil degradation caused by cultivation.

Soil property	Criteria for recognizing degradation: Typical causes and consequences
A horizon thickness	Decreased thickness caused by water or wind erosion. Reduces important organic matter-enriched surface layer that can be exploited by plants for water, nutrients, and oxygen. Shallower depth to possible root-limiting subsurface layers such as strongly developed argillic horizons.
Soil structure	Macromorphology: lowered grade of granular or subangular blocky structure, trend toward massive state, especially in surface horizons. Commonly results from compaction and organic matter decline.
Bulk density	Compaction (increase in bulk density above that of natural condition) associated with degradation in soil structure. Compaction and structure degradation commonly retard seed germination and root growth, reduce root access to water, oxygen, and nutrients, reduce diffusion of gases, and decrease water infiltration and available water capacity.
Organic carbon	Decrease in organic C is common under conventional cultivation. Results from accelerated microbial oxidation of organic matter in disrupted, exposed soil aggregates, and other effects of agriculture. Numerous benefits of organic matter for soil physical, chemical, and biological properties important to plant growth are well documented.
Nitrogen	Decrease in total N accompanies declining organic matter in agricultural soils, though C:N ratio tends to decrease. Nitrate and ammonium are plant available forms of N, which is commonly a key limiting factor for plant growth in all regions, including arid regions.
Phosphorus	P (both total and available) is another macronutrient that has been shown to decrease due to cultivation in some cases. Phosphorus is a key ecological and soil indicator because of its low mobility, low availability to plants, and long-term stability of its forms in soils.
pH	Very high soil pH can indicate salt accumulation (which is measured by electrical conductivity). Sodic soil conditions (recognized by high exchangeable sodium) can be prevalent in agricultural soils of arid and semiarid regions. Acidification and low pH is common in humid and tropical environments due to intensive leaching and weathering. Detrimental effects on many plants, including crop species, occur both through direct chemical effects and through soil structural deterioration. pH is also an indicator of the availability of nutrients to crops.

Adapted from Brevik EC, Homburg JA, and Sandor JA (2018) Soils, climate, and ancient civilizations, in Horwath WR, and Kuzyakov Y (Eds.), *Climate Change Impacts on Soil Processes and Ecosystem Properties*, pp. 1–28. Developments in Soil Science, vol. 35, Elsevier B.V. Amsterdam.

Sustainability and degradation

Mesopotamia is a classic example of anthropogenic land degradation that contributed to civilization collapse, but along the southern reaches of the Tigris and Euphrates rivers agriculture was sustained for five millennia (3000 BCE to 1980 CE) based on the production of dates (*Phoenix dactylifera* L.), vegetables, and water buffalo. High concentrations of N and P in soils indicate a slow buildup of organic-rich materials through anthropogenic activity. This lifestyle lasted until large-scale dams were built on the Tigris and Euphrates and marshes were drained in the 1970s and 1980s (Fitzpatrick, 2004).

In his classic work “Farmers of Forty Centuries,” King (1911) noted that despite dense populations and relatively little arable land, civilizations in eastern Asia managed to sustain agriculture for 4000 years. King attributed their success to several factors: (1) abundant rain and long growing seasons that allowed multiple crops per year, (2) intercropping, (3) matching crops to local conditions, (4) good water management that combined irrigation and dryland cropping systems on the same land, depending on season, (5) using mulch for water conservation during drier periods, and (6) using multiple nutrient sources as fertilizers (e.g., green manure, compost, ash, animal and human manure, and legumes in crop rotations). King concluded that the favorable climate was essential for sustaining East Asian agriculture. The obvious corollary is that climate change could undermine the sustainability of these practices. Paddy soils in Asia have a number of unique properties because of the alternations between being saturated and drained over time, which cause anaerobic and aerobic conditions and reduction and oxidation processes in the soil. The result is elevated organic matter levels, altered mineral weathering and clay formation, acidification, puddled surfaces, albic E horizons, and redoximorphic features (that is, iron and manganese depletions and concentrations) where water levels fluctuate.

Some agricultural soils in the Andes Mountains of South America have been cultivated for at least 1500 years and still remain productive (Sandor and Homburg, 2017). Although located in steep mountainous terrain, terraces were built to create gentle slopes for arable land and provided a way to manage irrigation. Manure and ash from fire hearths were incorporated into terraced soils. These practices created thickened A horizons in terraced soils that had lower bulk density and elevated C (carbon), N (nitrogen), and P levels compared to nearby, natural uncultivated soils on steep mountain slopes. However, some researchers have questioned the sustainability of these terrace systems during prolonged droughts (Branch et al., 2007). One important lesson here is that a given system may be sustainable under some climates, but not others.

Unfortunately, there are many examples of soil degradation in human history, with one of the most cited examples being Mesopotamia. Sumerians irrigated successfully for a long period, but their civilization declined as soils became too saline and waterlogged for crop growth due to salts in irrigation water and rising groundwater levels caused by irrigation (Hillel, 1991). The Babylonians rose to power after the Sumerians until Babylonian canals filled with silt eroded from surrounding hills, triggered by forest clearance from hills around river valleys to obtain timber and create grazing areas for livestock (Troeh et al., 2004). Along the borders of southern Iraq’s marshlands, the same location where agriculture persisted for five millennia, rice was produced as early as 550 BCE. Accelerated sedimentation covered rice fields over time so that fields were abandoned and new rice fields created, leaving large expanses of unproductive land behind. This example shows how proper water management and soil conservation are critical to sustainable agriculture.

Another classic example of cultural collapse due to soil degradation and resource exploitation is found on Easter Island (Rapa Nui), where Polynesian settlers began shade gardening in forests about 1200 CE but shifted to intensive dryland farming as extensive deforestation and soil erosion occurred within a century of occupation (Sherwood et al., 2019). These early settlers arrived on an island vegetated by mesic forest including palm trees (*Paschalococos disperta* Dransfield), but deforestation was nearly complete by 1650 CE. Sweet potato (*Ipomoea batatas* (L.) Lam.) was their main staple, but other crops included banana (*Musa* sp.), taro (*Colocasia esculenta* (L.) Schott), paper mulberry (*Broussonetia papyrifera*, Syn. *Morus papyrifera* (L.)), and in all likelihood, bottle gourd (*Lagenaria siceraria* (Molina) Standl.) (Sherwood et al., 2019). Soils at many sites were degraded on the island, mainly by leaching and loss of nutrients, especially P, whereas others remained fertile in localized area, especially soils formed from the weathering of lapilli tuff, a type of volcanic pyroclastic. At one time Easter Island may have supported a population of as many as 10,000 people, but by 1650 CE the population had declined and the society collapsed. When James Cook visited Easter Island in 1774, he found about 1000 people only. Hypotheses for explaining the collapse on Easter Island include: (1) overexploitation and degradation of the island's resources, especially palm trees, but also soil and water resources, (2) contact with European explorers who spread disease vectors, and (3) environmental changes beyond human control. Of these, the first seems the most likely cause. If true, Easter Island shows what can happen when humans abuse ecosystems. If the third hypothesis is true, it serves as a warning regarding the potential impact of environmental changes such as climate change. It is also possible, if not likely, that a combination of factors is the best explanation. This is a sobering possibility as we contemplate a modern world with an environment that is degraded in many ways coupled with a changing climate.

Climate change and ancient cultures

Both climate and climate change have strongly influenced human societies throughout history. Warmer climates at the end of the Pleistocene facilitated the beginnings of agriculture and complex societies. Many early civilizations in both the Old World (Mesopotamia, Egypt, Indus, Greece, Roman Empire, and other places in Asia, Africa, and Europe) and the Americas (Peru, highland Mexico, American Southwest) arose in arid regions. Favorable climates provided conditions for past societies to take root and flourish. Climate change, especially prolonged drought, has been implicated as a critical factor in the demise and collapse of some civilizations in the past.

Some civilization failures were probably caused by a combination of climate changes and cultural factors. A prime example were the Norse people in Greenland. The climate in Greenland was unusually mild when the Norse first settled Greenland in the late 900 s CE, followed by the onset of the Little Ice Age about 1300 CE and complete abandonment of Norse settlements in Greenland in the 1400s CE. Clinging to cultural traditions has been suggested as an explanation for the failure of Norse settlements in Greenland as the Little Ice Age brought on a colder climate (Fig. 2). Debate exists over whether soil degradation was a problem for

Fig. 2 Standing architecture of the Hvalsey Church and associated masonry rubble from collapsed farm buildings in an ancient Norse settlement in southern Greenland. Courtesy of Wikipedia: https://en.wikipedia.org/wiki/History_of_Greenland#/media/File:Hvalsey_Church.jpg.

Norse settlements in Greenland, with some researchers concluding there is no evidence of significant widespread soil degradation while others have concluded erosion was a significant problem in at least some locations (Brevik et al., 2018). There are, for example, buildings at some sites that were buried by drifting sand, likely to have been initiated by overgrazing. However, there is little debate that climate played a role in the Norse demise. The abandonment of Norse settlements in Greenland in the 1400s CE after the onset of the Little Ice Age led many researchers to conclude that the Norse settlements in Greenland failed due to climate. Studies indicate a change in diet from primarily terrestrial food sources to greater dependence on marine food sources during the Norse presence in Greenland; a cooling climate is one reason that may have spurred this dietary shift. Despite adjustments such as a shift in diet, the Norse settlements in Greenland eventually failed. It is noteworthy that Inuit communities, by contrast, were able to survive the same climate change that the Norse settlements in Greenland could not. The decline of the Norse Greenland settlements was probably caused by a combination of climate change and a conservative culture that was resistant to change, leaving the Norse vulnerable to environmental alterations. The message from this for the future is that land degradation is not the only challenge to the persistence of a civilization, cultural inflexibility may also be a serious liability in a world of changing climate.

Societies may not only be negatively affected by climate change in an absolute sense, but also by increased climate variability and unpredictability. Previous climate change during the Holocene that has affected societies globally (e.g., the Medieval Warm Period and the Little Ice Age) or regionally are attributed to oceanic and atmospheric circulation cycles such as the El Niño-Southern Oscillation, cyclic and episodic changes in solar radiation, and volcanic activity. Humans must now be added to this list of drivers of climate change.

Climate change is a significant factor in social change in the past and present, but it is also important to recognize that causes for the rise and fall of societies involve complex interacting social, economic, and environmental variables, not just climate change. Views that climate change determined past social change are too simplistic because societies are not passive in the face of environmental change and variability, but actively respond and adapt (Kirch, 2005). Determining the cause(s) of past social transformation or collapse is controversial. This complexity in the interaction of humans and environment is evident in the wide range of human responses to climate change over space and time. Some environments are inherently riskier than others, and some societies have been more resilient than others. Archeologists distinguish different degrees of vulnerability of societies to instability and failure in the face of environmental change and other pressures. Some societies that lacked the flexibility to respond to environmental change were caught in a 'rigidity trap.'

It is also important to recognize the challenges in measuring and interpreting past climate change in studies of ancient societies (Ingram, 2015). A number of tools exist for reconstructing paleoclimate (Fagan, 2008) with varying degrees of accuracy and precision, and multiple independent approaches are important. Even the finest of these climate markers, such as tree-rings, which provide precipitation and temperature data on an annual scale, are still too imprecise for reconstructing conditions during crop growth, such as during the stages of maize development withing a growing season.

Cases from several world regions, climates, and cultures illustrate the broad range of climatic and environmental impacts on water resources, conditions during the crop growing season, and food production encountered by past societies. These include many combinations of environmental and social conditions, and outcomes for past societies. Some researchers have identified collapses in ancient societies in which severe drought played a significant role. These have occurred in northern China, the Indus Valley, Mesopotamia, Peru and the Andes, the Maya region, and North America (Dunning et al., 2012; Fagan, 2008; Montgomery, 2007). Societal collapse has involved political upheaval, conflict, and long-term depopulation. To illustrate the complexity of social transformation in relation to climate change, the drought of the mid-1100s AD in the American Southwest associated with the demise and depopulation of Chaco Canyon affected other Southwestern cultures in the Mesa Verde and Mimbres areas (local population shifts) differently (Ingram, 2015). In some cases, systematic demographic and land use change in response to climate change has been a consistent component of some social structures, as in the 'verticality' adjustments of Andean people and the movement of agriculture to higher elevations with more moisture during drier periods or to lower elevations during wetter periods.

There are a number of cases in which ancient and traditional societies were able to respond successfully to climate change and remain in place. Of potential relevance today are the innovations developed by past peoples in actively adapting to climate challenges and change, including new technologies, crops, and agricultural strategies. For example, varieties of maize were developed in the Americas that were adapted to aridity or high altitudes. In the American Southwest, desert plants such as agave (*Agave* sp.) were domesticated in part to offset food shortages when other crops failed. Several of these adapted crops, the landscapes on which they were grown, and the techniques by which they were managed are not used today but have potential (Sandor and Homburg, 2017). One of the most important principles in adaptive traditional agricultural systems is their diversity in terms of crops and field location. Agricultural diversification is a deliberate strategy of risk management in the face of environmental vagaries. Strategies of landscape risk management for climate variability, widely practiced in arid regions such as the American Southwest, include spatially diverse field locations, combinations of irrigated agriculture in valleys with dryland farming at valley edges and in uplands, and specially adapted crops and crop management, combined with food storage techniques. Irrigation agriculture may have been the mainstay, but upland production could protect the soil against damaging floods or freezes relative to fields in valley floors that must cope with cold air drainage risks. Innovative technologies developed in response to climate fluctuation, water scarcity, and climate change-related hazards such as soil erosion. Solutions to these problems include agricultural terraces, lithic mulch and rock configurations for concentrating and conserving soil moisture and moderating temperatures, water harvesting, wells, and qanats (gently sloping underground channels with vertical shafts used to access and transport water from groundwater to agricultural fields).

Climate change not only impacts societies directly, but also through complex interactive effects among hydrologic, geomorphic, and soil processes, and vegetation change. Positive or negative outcomes in terms of impact on agriculture and society are possible,

Fig. 3 1930s Dust Bowl on the southern Great Plains, USA. (A) massive dust storm during the Dust Bowl. (B) heavily eroded agricultural fields and windrow of redeposited topsoil along a fence line eroded from agricultural fields left in the aftermath of a dust storm. Courtesy of the United States Department of Agriculture, Natural Resources Conservation Service, USA.

but negative outcomes are more likely. For example, stream channel widening and incision caused by climate change after centuries of geomorphic stability played a role in reorganization of the prehistoric Hohokam society in the Phoenix Basin of Arizona by disrupting extensive canal irrigation systems (Waters, 2006).

Another key point is that it can be difficult to separate the causes of land degradation from either natural climate change or anthropogenic impacts because they often operate together through feedback processes. Degradational effects of climate change may be triggered by anthropogenic landscape and ecological change or vice versa. There are instances in which climate change may not have caused landscape degradation such as accelerated erosion had it not been preceded by anthropogenic change. An added dimension to this today is human-induced climate change.

Researchers infer a link between climate change and anthropogenic environmental change that has negatively affected many past societies. Soil-geomorphic and ecological degradation associated with climate change and agriculture has been documented in several world regions. Common examples include accelerated soil erosion in sloping agricultural lands in China, Europe, the Mediterranean and Middle East, the Mayan area, and the American Southwest (Butzer, 1982; Hillel, 1991; Kennett and Beach, 2013; Kirch, 2005; Montgomery, 2007; Nabhan et al., 2020; Sandor and Homburg, 2017). A historic example is the Dust Bowl in the U.S. southern Great Plains, where extensive clearing and cultivation of prairie soil combined with a periodic drought led to severe wind erosion, land abandonment, and depopulation (Montgomery, 2007) (Fig. 3).

Climate change, now linked with human causes, presents serious challenges to societies today. The failures and successes of ancient societies in their land use and response to a wide range of climate and environmental change can provide valuable long-term insight for addressing current problems such as water supply and agricultural production under difficult and variable climate conditions.

Conclusions

Many scientists now consider that we are living in the Anthropocene, an age when human influences at a global scale have become so pronounced and pervasive that humans are the single most defining geologic force of the era (Zalasiewicz et al., 2015). This influence has made many soils human-natural bodies rather than just natural bodies (Yaalon and Yaron, 1966). Another effect of humans on the natural system has been our influence on changes to global climate. Soils are changed by climate and, in turn, influence climate. Consequently, as we seek to understand how living in a world of changing climate may affect modern civilizations, understanding how soils will respond, and how that affects humans is imperative. One approach to undertaking this task is to model what the future will look like given the changes that we expect to see. However, human civilizations have a long record of living under changing climates in the past. Through interdisciplinary and transdisciplinary studies that link soil scientists, archeologists, and other scientists, we can gain a more holistic understanding of the impact of climate change on past human societies and natural resources such as soils that they depended on and have the opportunity to observe those impacts. By paying attention to and learning from our past, we can improve the models that aim to predict our future and plan to manage and minimize potential impacts better.

Abstract

Land under human influence, such as urban, industrial, traffic, mining, and military areas are characterized by a great diversity of soils with specific properties. Some are close to natural soils, but most are greatly modified or even deliberately constructed. These soils of highly anthropized areas render a wide range of ecosystem services, provided that their functions (e.g. carbon storage, habitat for biodiversity) are not altered or that restoration operations are carried out.

Introduction

Soils in highly anthropized areas, such as in cities, industrial complexes, along streets, railways, at airfields, in open pits or underground mining areas and in areas used for military actions can perform a wide range of functions of primary interest (Levin et al., 2017). In cities for instance, they support human activities, e.g. habitat, stable ground for housing, industrial activities, transport and greening. These functions are primarily considered and widely accepted by landowners, policy makers, and city dwellers as they offer monetary income and a minimum of wellbeing.

With emergence of the concept of ecosystem services (MEA, 2005), efforts to identify the greatest number of contributions to the mitigation of global change (e.g. climate, biodiversity), ensuring well-being and prosperity of citizens have led to questions about the role of soils in anthropized areas including those greatly modified by human activities. These soils are primarily found in urban areas, but also in industrial, traffic, mining, and military areas (Burghardt et al., 2015). In view of the great diversity of locations where soils are profoundly affected by human activities, in 1998, Burghardt and Morel proposed SUITMA to designate heavily modified Soils in Urban, Industrial, Traffic, Mining, and Military areas (Burghardt et al., 2015). This definition emphasizes the location of soils, i.e. very heavily anthropized areas, rather than their specific characteristics. The acronym was launched at the 18th World Congress of Soil Sciences held in Montpellier, and scientists who dedicate their research to these soils have been meeting every 2 years since at the SUITMA conferences. Despite the impacts of human actions on the properties of such soils that can lead to some degradation, SUITMAs can provide a wide range of services, namely habitat, provisioning, regulating and cultural services (to humans).

Among anthropized areas, cities are of particular interest because most of the world's population now lives in them. It was only in the last two decades that urban soils have attracted increasing interest from policy makers, municipalities, and soil scientists.

Fig. 1 Cities as they appear on soil maps (here city of Nancy, France) – from Soil map of France, GIS Sol – RMT *Sols et Territoires*, 1/250000 – legend: gray: city; yellow & orange: soils on limestone material; green: soils on alluvial material; dark brown: soils on loam.

Of course, they were not ignored in the past (e.g. Bastie, 1965; Blume and Runge, 1978; Burghardt, 1994; de Kimpe and Morel, 2000), but often considered marginal and, therefore, set aside or even referred to as ‘non-soils.’ Cities, due to the challenges that their complexity induces for soil science and soil mapping, are however still depicted with gray or white spots on soil maps (Fig. 1).

Global soil map resources such as S-world or SoilGrids ignore urban soil information by masking urban areas (Poggio et al., 2021) (Fig. 2).

Also, emblematic, one of the earliest scientific publications on urban soils was not about the ecosystem services they provide, but about their contamination status (Purves, 1966). But now they are recognized as soils with specific characteristics of primary importance, especially in cities (Riddle et al., 2022).

In this chapter, the existing and potential role of SUITMAs and especially of urban soils as providers of ecosystem services in areas dominated by humans as the main controlling factor of the environment are discussed. After giving definitions, special emphasis will be placed on the main characteristics of soils, and the state of their functions will be described. Finally, the ecosystem services provided by highly anthropized areas will be presented, including the services linked to the mitigation of global climate change.

Definitions

Specific features of soils of highly anthropized areas

Three main features characterize the soils of highly anthropized areas: (i) the presence of technogenic material, (ii) sealing, and (iii) soil construction.

Technogenic material: in addition to soil material of natural origin, other compounds are intentionally introduced into soils, e.g. for road construction, waste deposition, dumping of dredged sediments, soil remediation etc. – or accidentally accrued during the city's history which can be as long as 6000 years. The so-called 'cultural layers,' usually containing construction and demolition debris, can have a thickness of several meters and store considerable amount of carbon, nitrogen and phosphorous, also pollutants and artifacts, i.e. materials created, substantially modified or brought to the surface by humans (Mazurek et al., 2016). Cities often grew on their own 'ashes.'

Technogenic material in soil science is material that is of (i) natural origin but not in its autochthonous location; it may show natural layering, evidence of transport and dumping by vehicles, pumps or bulldozers. This can be dredged material from rivers pumped to a new site, bedrock in mining areas dumped in heaps or tailings or topsoil material from other sites (e.g. transported material); (ii) material that is itself the product or byproduct of technological processes, i.e. an artifact, which is not found in nature like concrete, steel, bricks, or even limestone from chemical processes having a purity which cannot be found in nature; (iii) mixtures of both (i) and (ii).

Soil sealing is defined as the destruction or covering of the ground by an impermeable material.¹ Sealing is the strategy that paves the way for the beginning of colonization and civilization. Paved roads date back to 6000 BCE in the city of Ur in Mesopotamia. Paving is now well established in most cities around the world. In the more recent past, it made it possible to go from unsanitary streets, with mud, waste, smells, to clean sidewalks with sewers, where moving from one place to another in the city became easier and more comfortable, and where life in general became healthier (pandemics like diarrhea, typhus and cholera were reduced). These soils are thus designed to fulfill transport functions for the city at the expense of ecological functions. Pavements require the implementation of a series of technologies, which contribute to stabilize the soil, allow the introduction and concealing of wires, tubes, pipes, etc., and finally allow the circulation of humans and goods either on foot or with vehicles ranging from donkey carts to heavy trucks. However, soil sealing is considered one of the main causes of soil degradation and flooding in the European Union (EU), where more than 2.3% of the EU territory is now covered with an impermeable substrate (Corine Land Cover, EU soil map). Soil sealing is a primary issue regarding the destruction of important soil functions, e.g. water infiltration and runoff, biodiversity, local climate. The functioning of soils as a component of the urban ecosystem, including water flows and root paths under the impervious surfaces, is not well established.

Soil construction: constructed soils are defined as deliberate mixtures of technogenic materials that are associated and implemented to meet specific requirements (Deeb et al., 2020). Constructed wetlands, green roofs and green walls are examples of deliberately designed and constructed soils in urban areas. They are developing rapidly and promise to meet citizens' needs for greener and cooler streets and buildings. For example, urban green infrastructure contributes to a comfortable urban microclimate by cooling air temperature and increasing air humidity (Deeb et al., 2020). Another example is the construction of soils on degraded sites to restore their functions and to seek the conditions for the development of a new ecosystem (Séré et al., 2010; Slukovskaya et al., 2019). These examples will be detailed later to outline the consequences on ecosystem services.

Soils of highly anthropized areas

Anthropogenic soils are created or heavily modified by humans. Highly transformed soils are not only found inside cities, i.e. urban soils, but in every place where human activity is carried out and is converted into an artificial environment. The soil is one of the first components to undergo profound modifications. To highlight the importance of the human factor in the formation and evolution of soils in highly anthropized areas, the soils are identified and grouped according to their location, i.e. SUITMA.

Urban soils: are anthropogenic soils, located inside urban areas (recent or old) (Morel et al., 2005). These soil types are strongly heterogeneous, and are developed from natural, anthropogenic, or naturally occurring but anthropogenically displaced materials or mixtures of both. They show a change in soil properties due to anthropogenic impacts such as sealing and intensive use (Blume, 1992). They are developed from a mixture of materials that are different from the surrounding non-urban soils. Thus, urban soils are named to categorize and group them by their most obvious common characteristic, their location in urban areas. The National Resources Conservation Service (USDA, USA) defined urban soils as follows: "Urban soils are found in watersheds that provide drinking water, food, waste utilization, and natural resources to communities. Urban soils also are located within cities in park areas, recreation areas, community gardens, green belts, lawns, septic absorption fields, sediment basins and other uses" (USDA, online). Here, implicitly the interrelation of soils and their use are highlighted. In urban areas, most soils are simply managed to contribute to the urban landscape, and they are shaped without considering their functional roles in urban ecosystems. This is the case of soils from construction areas, which support lawns, trees, playgrounds, roadsides, etc.

Unlike natural soils, forest soils or agricultural soils, the anthropogenic impact can - if any - only be reconstructed with the help of history. The effects are understandable in retrospect but not logically or predictably so, and in summary urban soils could often be

¹<https://esdac.jrc.ec.europa.eu/themes/soil-sealing>

described as chaotic. However, urban soils have developed from 'natural soils' (including arable land, forests, wasteland). Unlike agricultural soils, urban soils are characterized by multiple different disturbances for different purposes. They have been and are subjected to extractions, additions, mixing, compaction, leveling, contamination, drainage, and sealing. Some of their original horizons have been completely removed by the excavations. Natural soil horizons may also be buried by excavated material or technogenic material transported from elsewhere. As a result, spatial patterns of urban soil properties are determined by a complex combination of conventional (e.g. elevation, vegetation, geomorphology) and city-specific (e.g. functional zoning and urban history), which determine an uneven spatial structure and a unique spatial variability of urban soils even at short distances.

(Pseudo)natural soils: in addition to highly anthropized soils, there are soils in the urban environment that have been only slightly altered by human activity. They are still very close to the original natural soils from which they developed, but they show changes due to urbanization. These might include compaction, the presence of artifacts, a different water regime and, in general, exposure to higher average and maximum temperatures than in their original environment. Thus, in cities, markedly transformed soils coexist with (pseudo)natural soils, the latter being found mainly at sites unsuitable for construction or in protected areas such as urban forests, parks, home gardens and community area (e.g. Tiergarten Park in Berlin, Germany, a former hunting reserve of the Dukes and Kings of Prussia which has become a public park)

Industrial soils: they are soils like those in urban areas, but with very specific characteristics due to the various operations that have taken place during industrial activity. Industries are often built near natural or man-made bodies of water. Consequently, their installation requires not only waterproofing but also the contribution of considerable quantities of materials to stabilize and level the surface, but also to avoid any threat linked to flooding by neighboring waters and high groundwater levels. In general, wastes from industrial activity are (minimally) managed directly on site. Lack of knowledge or awareness results in tailings, heaps and ponds of solid and liquid materials, intermediate by-products and wastes for storage or disposal. Some of the waste contains contaminants which, after industry closure and future use of the site, must be removed or inactivated to ensure safe redevelopment. Remediation is based on physical (e.g. thermal desorption, soil venting), chemical (e.g. chemical oxidation or reduction, soil washing) and biological (e.g. biodegradation, phytoremediation) treatments. Each of the technologies has a specific effect on the composition of the soil and its further operation. For example, thermal desorption removes most of the organic matter and leaves a biologically dead, mostly structureless mineral residue, while phytoremediation in general improves soil fertility and accelerates ecosystem restoration at the cost of a long remediation time.

Soils under traffic: these are typically drained, levelled, and compacted soils and their paving. Most of them are sealed soils, as defined above. Along the roads, water is re-directed and infiltrated or drained into sewers. Traffic-specific contaminants are dusts and soot from exhausts of trains, lorries and cars, particulates from rails, wheels, tires, brakes, pavements, and mechanical abrasions of metals due to friction in all parts of the vehicles. Furthermore, railways and roads are managed to be free of vegetation and ice by application of pesticides and deicing salts.

Mining soils: open pit mining greatly affects soils over very large surface areas. Historically, mining activities have led to the foundations of cities, some of them with a short peak of activity (e.g. Dawson in the Yukon, Canada) others where mining began a long and prosperous history (Freiberg, Clausthal-Zellerfeld, Germany; Zhelesnogorsk and Norilsk in Russia). After closure, mining sites must often be remediated and restored, the original soils can seldom be recovered. Another trajectory is then followed toward the development of a new ecosystem. Remediation of mining sites is based on soil engineering, i.e. on all the procedures and processes developed from the knowledge of soil science and environmental engineering to create new soil profiles whose functions have been improved and, if possible, could get as close as possible to those of the natural soils. With their small organic matter content, strategies are generally based on the addition of organic amendments, e.g. compost, manure, or materials excavated from natural soils. Nowadays, to preserve natural soils, the remediation of mining sites uses secondary materials which are recycled such as manure and compost (Guo et al., 2022).

Military soils: military operation is another human activity with a strong effect on soils. Either effective war or military maneuvers destroy original soils and introduce materials and contaminants (e.g. trace elements, radionuclides, toxic organic compounds). An example is the Verdun area (NE France on banks of Meuse River) which was strongly impacted during World War I. After one century, the soil has evolved toward the original soil type but still contains many artifacts, archives of the dramatic period. Unfortunately, today and in the past wars cause considerable damage to soil properties and functions, relocating soil and introducing technogenic materials (Rawtani et al., 2022).

Soil formation in highly anthropized areas

In anthropized areas, after the original natural soil genesis, soil formation after urbanization is mainly controlled by the human factor (Figs. 3A and B). Human activity controls the parent material (e.g. composition, compaction), transforms the landscape (e.g. relief, water dynamics), introduces and controls plants and animals and, in cities, generates specific climatic conditions (e.g. heat island effect). Therefore, pedogenic processes in SUITMAs are mainly under human influence. However, as discussed in another chapter of this book (Huot and Morel, 2023), processes observed in SUITMAs are like those described for natural soils (Huot et al., 2015). In short, the dominant processes are accumulation (e.g. organic matter from vegetation), transformation with alteration of the primary phases and neoformation of minerals, oxidation–reduction reactions, decarbonization, and transport, such as leaching (e.g. sulfates, carbonates), and precipitation into deeper layers (e.g. secondary calcite). Many other processes may also occur depending on the composition of the parent material. The specificity of the pedogenic evolution of heavily anthropized soils is the coexistence of processes that never or rarely occur simultaneously in the natural environment, such as, for example, the

Fig. 3 (A) Soil formation in highly anthropized areas (drawing J.L. Morel). (B) Concept of urban soil genesis depicting the importance of anthropogenic disturbances and their highly dynamic conditions for the existing soil (drawing T. Nehls).

decarbonation or carbonation observed together with andosolization, particularly in the presence of industrial sludge (Huot et al., 2015). Unlike natural soils, SUITMAs are young, poorly evolved soils because the parent material subjected to pedogenesis is mostly recent. As a result, very anthropized soils are characterized by an A/C type profile, which can evolve toward A/B/C soil horizons. In addition, with the presence of finely divided material, i.e. highly reactive material, a rapid differentiation of horizons during the early stages of pedogenesis can be observed.

In the following sections, we summarize the state of knowledge on urban soils, their formation, general characteristics, functions, and role in the urban ecosystem as a provider of ecosystem services, and the means to improve and to restore services from degraded land.

Common characteristics of soils in anthropized areas

Non-sealed soils are characterized by specific characteristics compared to natural soils (Riddle et al., 2022).

Composition

Despite the great diversity of soil types, SUITMAs have common characteristics. They are mainly composed of coarse materials. They can contain many anthropogenic materials, also called 'artifacts,' which are derived from rubble and various wastes (e.g. concrete, asphalt, bricks, glass, ceramics, oxides, plaster, plastic, coal, wood, waste, ballast) and industrial materials (e.g. slag, mine waste, dredged sediments, rock waste). There are also natural coarse materials, such as aggregates, sand and gravel, widely used in construction operations. Among the artifacts, some have properties likely to interfere with the fate of contaminants, metals, organic molecules, pathogens including viruses. An example is brick, which is mainly present in the coarse fraction and has a very dense internal pore system, giving a high water-holding capacity and the possibility for organisms to enter the pores (roots, fungi, bacteria, virus) (Fig. 4). Bricks are widely present in the soils of anthropized areas around the world.

Fig. 4 Biological functions of bricks (Nehls et al., 2013).

The pH

The pH values of soils are, in general, higher in urban areas than in rural areas (Fig. 5). This is due to the presence of large amounts of carbonates in anthropized areas such as cities and traffic areas but also, to a lesser extent, industrial areas. An example is the use of lime for road construction which increases soil pH significantly in acidic areas (e.g. Andosols, Kida and Kawahigashi, 2015). Materials for housing construction are also very rich in carbonates (e.g. concrete). With their high pH values, the physical and chemical properties of urban soils are therefore different from those of natural soils in the same region. Consequently, their functioning, both physically (structure) and chemically (reactivity, availability of elements, fate of charged particles), and biologically (e.g. microbial activity), is very specific. They could be similar to soils developed on natural calcareous materials and function like these soils (e.g. dynamics of nutrients, P, trace elements; organic matter).

Organic matter

The organic matter composition of SUITMAs is highly variable. Some have a large organic matter content (e.g. disposal of combustion residues and organic waste, soils used for horticulture). Black carbon, a very stable organic material produced by incomplete combustion (e.g. heating, fires, vehicle emissions) also accumulates in urban soils, thus contributing to a high percentage of soil organic carbon (e.g. 28%; Nehls and Shaw, 2010). Other soils contain small concentrations of organic matter, for example after the removal of topsoil by civil engineering (e.g. road and building construction; mining). Others may contain a large amount of very stable C (e.g. petroleum hydrocarbon, polycyclic aromatic hydrocarbons, PAHs) which can be found very deep in the profile of industrial soils. Global reviews showed: (i) higher C stocks in urban soils compared to the natural counterparts with an especially high variability in high latitudes (Vasenev and Kuzyakov, 2018); (ii) that Technosols, despite their high variability, are among the soils with the largest organic carbon stocks on Earth (Allory et al., 2021).

Fig. 5 The pH in French topsoil according to land use ($n = 2450$) (Joimel et al., 2016).

Contaminants

Most SUITMAs contain contaminants, either organic (e.g. hydrocarbons, polychlorobiphenyls PCBs) or inorganic (e.g. metals), or both. They come from all urban and industrial activities (e.g. traffic, wastes). In general, soils of anthropized areas exhibit higher concentrations of contaminants than in other areas (Fig. 6). Gardens are particularly exposed to contaminations, and, on average, there is twice the concentration of metals in garden soils than in agricultural soils (Schwartz et al., 1995). The contaminants react with the solid organo-mineral phase of the soil. This results in a partition between the two solid and liquid phases, which determines their fate. They can be degraded (organic contaminants), immobilized (precipitation, sorption, absorption, complexation), or introduced into the soil solution where they can be transferred to different targets (e.g. organisms, groundwater). Soil composition and properties (e.g. clays, organic matter, pH, redox potential) are key factors that determine the fate of pollutants in soils. In urban soils, because of their high pH, the risk of transfer of 'heavy' metals to targets such as plants is low. On the other hand,

Fig. 6 Cadmium in French topsoil according to the land use (Joimel et al., 2016).

soil particles (e.g. clays, silts) carrying contaminants can be transported in the form of dust and contribute to the exposure of nearby population to toxic compounds or even pathogens that can affect their health. These factors also play similar roles with respect to charged viral particles. Salinization by de-icing reagents is another threat, which urban soils in cold and temperate climates are exposed to. Large concentrations of soluble salts suppress soil microbiota and damage root systems (Gavrichkova et al., 2020).

Diversity of soils in anthropized areas

Anthropization produces a large diversity of soils

SUITMAs cover a wide range of soil types. The main reason is the variety of parent materials from which they derive. These parent materials come from the numerous mixing, compacting, leveling and sealing operations of the initial materials, and from the export of earthy materials and import of exogenous materials (e.g. soils, waste). As a result, soil diversity in heavily anthropized areas is greater than in agricultural areas where operations tend to standardize soil properties (Fig. 7A). Soil formation and evolution in highly anthropized areas remain, however, linked to the climatic conditions as observed along a latitude gradient (Fig. 7B).

The urban soil mosaic

Cities are characterized by the 'urban soil mosaic' (Pouyat et al., 2010), which is clearly represented on soil maps (e.g. New York City; Fig. 8). City soil maps are an important link between soil science and city management, as they provide useful information for decision makers to optimize land use, and provide a safe and good quality environment for city dwellers. For example, they can be used to provide an inventory of soil properties in open spaces to manage municipal water and sewers, control soil pollution, identify wetlands and wildlife habitats, assist in park management, and understand the drainage, runoff and flow of urban streams (Shaw et al., 2007).

Classification

SUITMAs are considered in soil classifications, especially in the World Reference Base for Soil Resources (2022) (WRB). They are classified into three groups of WRB soils: Regosols, Anthrosols and Technosols. The Regosols of SUITMAs are young soils with an A/C type profile and are characterized by urban classifiers (e.g. urbic, spolic, technical, toxic, transportic). Anthrosols are marked by the presence of a large content of organic matter (e.g. horticultural soils) at great depth (e.g. hortic, irrigric, plaggic or terric horizon ≥ 50 cm thick). Organic matter has accumulated over the years by the application of manure, household waste, and charcoal. Old gardens with long and intensive horticultural use are examples of Anthrosols (Fig. 9).

Technosols are soils that contain a high proportion of anthropogenic materials, or artifacts, resulting from human technologies (at least 20% in the first meter of the profile) and/or a continuous impervious layer (e.g. geomembrane). This group was suggested by Lehman (2006) and Rossiter (2007). Constructed soils are classified as Technosols because they contain a large amount of technogenic materials, including transported soil material, wastes, sludges, etc. (Fig. 10). SUITMAs are also recognized by national classifications, German, French, Polish, USA, and Russian classifications, to integrate anthropogenic processes. The International Committee for Anthropogenic soils has defined Human-Altered and Human-Transported soils in Soil Taxonomy (Galbraith, 2018).

Functions of SUITMAs

Like natural soils, SUITMAs fulfill a wide range of functions (reservoir of nutrients, support for roots, reservoir of biodiversity, filtration and transformation of substances, storage, source of raw materials, physical support for human activities, archives). Pseudo-natural SUITMAs (e.g. parks, urban forests) that show little change (e.g. compaction) from the corresponding natural soils, perform most of these functions. But when anthropogenic factors tend to dominate the formation and evolution of soils, these functions can be seriously degraded. Soil sealing is an example of a degraded function that can cause dramatic damage to people and their property (Fig. 11). The case of floods illustrates the dependence of city dwellers on natural capital (stocks). The figure also shows the links between stocks, processes, functions and services and shows that it is possible to give an economic value to stocks in the event of flooding.

Examples of the status of three main soil functions in SUITMAs is presented below.

Support for roots

Root establishment and development is highly dependent on the physical properties of the soil. The presence of coarse materials, rubble, impermeable layers, large voids, contamination, excess water, etc. affect root development in SUITMAs. Again, sealing is a major obstacle for roots and a major disturbance for plants, such as trees. In the city, trees encounter very contrasting physical soil conditions whether they are in parks or have been planted along streets (Fig. 12).

Soil compaction can induce not only plant growth inhibition but also water stagnation and subsequent hydromorphic conditions. Soil porosity is generally significantly affected by the anthropization gradient (Fig. 13).

Fig. 7 Anthropization produces a large diversity of soils – (A) comparison between natural, agricultural and anthropized areas; (B) sequence of natural and urban soils according to the latitudinal gradient in Russia.

Reservoir of biodiversity

SUITMAs offer a wide variety of habitats for biodiversity. All groups of soil organisms are present in urban soils, i.e. earthworms, arthropods, nematodes, microorganisms, living under the specific environmental conditions of the urban environment (e.g. temperature, available water, compaction, contamination) (Guilland et al., 2018). However, they are notably different in composition, morphology, and functioning according to the gradient of anthropization from forest areas to urban areas (Fig. 14).

Soil degradation induced by former industrial activities includes contamination, presence of artifacts, small organic matter and nutrient content, low available water, etc. Such conditions are in general not favorable to organisms. From a survey of a set of brownfields, it was observed that the taxonomic microbial diversity was not significantly affected by the gradient of metal pollution (Lemmel et al., 2019). However, the metabolic functions showed a decrease along the gradient. Therefore, the biodiversity in soils of heavily anthropized areas exhibits specific features which open important perspectives regarding the role of soil organisms in the functioning of urban soils and hence of the urban ecosystem.

Fig. 14 Soil macrofauna along a gradient of anthropization (from forest to urban areas) (Joimel et al., 2016).

Fig. 15 Accumulation of carbon in soils of urban areas (Vasenev and Kuzyakov, 2018).

Carbon storage

Carbon accumulates in urban soils; the inputs originate from suburban areas (food, wood, raw materials, peat material) and bring large amounts of organic compounds into the city. Also, other forms of C other than organic matter contribute to the accumulation of C in urban soils from waste (plastic, rubber, soot, charcoal) and from construction materials (e.g. concrete). Over the years, this process leads to a significant increase of C in soil which was estimated to reach 20–30 kg m² per century (Fig. 15; Vasenev and Kuzyakov, 2018). Therefore, SUITMAs represent a potential carbon sink which could be relevant to contribute to C storage to meet the objectives of C neutrality by 2050, considering the huge surfaces of anthropized areas (e.g. parks and gardens, urban agriculture, green roofs and walls, roads, railways, airports, commercial areas, brownfields – mines and industry, military areas; <https://www.allianceenergie.fr/>).

Estimates of C in urban soils have been made showing a range of 6–10 kg C m⁻² in the first 30 cm of the soil profile (Pouyat et al., 2006). Forest land contains about 15 kg m⁻², and crop land less than 8 kg m⁻². The unsealed areas reached more than 18 kg C m⁻² while the sealed soils contained only 6 kg C m⁻². Similar figures were obtained by Cambou et al. (2018) for the city of Paris. At the same time, the resistance of these stocks to biodegradation can be rather low, especially under the urban heat island effect. For example, urban lawns on Technosols constructed from peat–sand mixtures in Moscow city were C sources, especially in the central areas where the heat island effect was the strongest (Vasenev et al., 2021). In addition, due to the presence of carbonated material and incorporation of charcoal, inorganic C in anthropized areas represents a significant contribution to C storage (Vasenev and Kuzyakov, 2018).

Based on a meta-analysis of carbon stocks in Technosols, two major origins of these anthropized soils have been highlighted: (i) the organic carbon stocks are very different from one Technosol to another, with an unparalleled variability compared to other natural soils; (ii) the distribution of organic carbon stocks over depth does not respond to the usual decrease with depth because many anthropized soils have a large organic carbon content in the deeper horizons (Allory et al., 2021) (Fig. 16).

Ecosystem services provided by SUITMAs

Like natural soils, SUITMAs provide a wide range of ecosystem services. In densely populated areas, SUITMAs are important for urban agriculture (e.g. horticulture, gardening, green roofs and green walls, parks and street trees), essential in the water cycle (e.g. urban hydrology, infiltration, water transport), sequestration of pollutants, in air quality regulation (e.g. PM, NO_x), climate regulation (emission of greenhouse gases, heat-island effect). They play a key role in supporting biodiversity in anthropized areas because they host plants and ecosystems (fauna, flora, microflora).

The potential to provide a wide range of ecosystem services, each at a high value, decreases with human pressure (Fig. 17). There has been a proposal to sort the different types of SUITMAs according to their ability to provide ecosystem services (Fig. 18; Morel et al., 2015). Four groups have been proposed, including pseudo-natural SUITMAs, represented by only slightly altered soils found in urban forests, constructed SUITMAs, including garden soils, constructed Technosols, green roofs, and SUITMAs in landfills, either for the disposal of municipal waste or industrial waste, finally the sealed SUITMAs, including paved soils and completely sealed soils.

Fig. 16 Distribution of soil organic carbon content with depth in Technosols and fitted models and boxplots of SOC* content for 0–10 cm, 10–30 cm, 30–60 cm, 60–100 cm and 100–200 cm of average sampling depth (Allory et al., 2021).

Fig. 18 Estimated value of ecosystem services provided by groups of SUITMAs (Morel et al., 2015).

Examples of two services provided by contrasting groups of SUITMAs, each resulting from deliberate construction are: (i) green roofs and (ii) sealed soils.

Green roofs and green walls are completely artificial soils. They are designed to fulfill several functions, and as such they are providers of a large range of services. Regulating services include mitigation of water flow, notably flood control, filtration of water, decrease of urban temperature through evapotranspiration, and thermal insulation of buildings, improvement of air quality through the capture of pollutants such as PM and NO₂. They also provide habitats for biodiversity, not only for plants but also for arthropods, birds, etc. Green roofs can also contribute to urban agriculture and provide provisioning services such as food (roof gardens). Green roofs contribute also to cultural (gardening and related social activities) and esthetic services. Attention should be paid to the quality of the materials that are used for the construction of green roofs, to avoid any leaching and dissemination of trace elements.

Sealed soils are designed to provide several ecosystem services to support the well-being of city dwellers through the supply of water and energy (hosts of pipes and wires) and support safe and clean transportation and habitat activities. They are also designed to manage rainwater and ensure a rapid disposal of runoff water. Soils in cities are also shaped to provide a smooth and attractive landscape, either sealed or vegetated soils, highlighting architectural heritage and pseudo-natural spaces. Overall, in all countries, soil sealing has been and remains mainly seen as a step toward a better life in the city. However, as mentioned earlier, sealed soils can also be detrimental. Among the issues are increasing risks of flooding resulting from loss of the infiltration function in the event of heavy rain, the loss of agricultural and forest land due to the conversion of natural soils into buildings, roads, parking areas, commercial centers, airports, etc. Also, the heat storage function is exacerbated and reinforces the heat island effect. Regarding plants, sealed soils offer a poor habitat for roots, and biodiversity is rather low. Sealed soil covered by dead plant leaves represents a threat for pedestrians during the rainy days of autumn. There are many questions regarding the functioning of soil in the deeper horizons, including water infiltration, development of roots, aeration, dynamics of elements and carbon, etc.

Restoration of soil functions to improve ecosystem services

Soil science knowledge combined with technical equipment has made it possible to develop new ways to restore soil functions of degraded areas. This dynamic was triggered by the considerable shift of the economy of many industrialized countries during the period of the 1970s–1990s, leading to huge areas of industrial wasteland resulting from industrial, mining, and military activities. Together with the conversion to new economic and residential activities, large areas have been left to evolve spontaneously. The strategy is based on nature-based solutions, in particular soil construction and agroforestry ecosystems (Fig. 19).

Fig. 19 From an unused degraded site to a valuable resource (drawing J.L. Morel).

Fig. 20 Soil construction principle (Séré et al., 2010).

Constructed Technosols are fully artificial soils that have been created to reclaim degraded sites (e.g. brownfields, mining sites). Such an operation creates new soil profiles whose properties and functioning are close or even analogous to those of natural soils (Séré et al., 2010; Fig. 20).

Soil functions are restored and enable the development of new ecosystems. Beforehand, such soil profiles were specifically designed to fulfill a set of functions that provided many ecosystem services from industrial and mining sites, initially poor in organic matter and nutrients, salinized, containing pollutants and artifacts, compacted, therefore unfavorable to root development, and more generally to life. Soil construction should be based on the use of secondary materials (e.g. urban and industrial wastes, treated earth), for which the content of contaminants (e.g. trace elements, organic compounds, pathogens) should be assessed before construction. This strategy makes it possible to reduce the excavation and transport of clean soil material collected from natural soils. Using secondary materials thus preserves agricultural and forest soils.

Constructed soil provides several ecosystem services, including provisioning (biomass), regulation (biodiversity, filtering and exchange, C storage, use of anthropogenic material to protect soil natural capital, local climate). A constructed Technosol implemented on a former coking plant (Gisfi, Homécourt, NE France) has demonstrated the capacity to provide several ecosystem

Fig. 21 Ecosystem services provided by a former brownfield site after soil construction (Lorver program, Gisfi, 2018; <http://lorver.org/accueil/index.html> (drawing J.L. Morel).

services in a similar or even better way than natural soils (Fig. 21) (Hedde et al., 2019; Rees et al., 2019). For the food supply service, fodder yields were like those rendered by neighboring agricultural soils. Woody species have been installed, contributing to the supply of biomass for industrial use (e.g. energy, fiber). The recovery of metals (e.g. nickel) can also be considered by agromining if the soil contains the element of interest. Construction of the soil, then development of the vegetation contributed to a significant carbon supplement, which reached 520 t C ha⁻¹ after 3 years, four times more than the analogous natural surrounding soils. The restored ecosystem has allowed the installation and development of many species (e.g. collembolas, nematodes, earthworms), with different kinetics depending on the soil organisms considered. Diversity and abundance were like those of referenced natural grasslands.

Conclusion

Anthropization generates a great diversity of soils with specific characteristics, pH, coarse texture, compaction, sealing, pollutants, etc. The multiplicity of human actions over time results in a mosaic of soils with differing characteristics at short distances. Until recently, the soils of highly anthropized areas (SUITMA) have been dominantly perceived as degraded and contaminated soils if not non-soils. However, they can fulfill a large array of functions of great importance in the urban ecosystem. These functions are the basis of several ecosystem services, among them local and global climate regulation (mitigation of the heat island effect, C storage), biodiversity habitat induced by the variety of soil types in the anthropized areas, and regulation of the water cycle.

Soil functions in anthropized areas, however, are frequently affected by the physical and chemical stresses that occur in densely populated areas (e.g. compaction, sealing, contamination). They have been disregarded until very recently for their role as a three-dimensional reactor in the urban ecosystem; these soils now represent an asset for city managers to improve the quality of life of city dwellers. With the growing interest in 'urban soils' shown by pedology, new knowledge is being acquired. Soil science devoted to urban areas is quite different from that of natural and agricultural areas. They differ in at least two ways, the first is a soil science oriented toward the prediction of soil evolution, i.e. the future of soils instead of the past, and the second is a practical aspect, i.e., soil engineering specifically designed to perform given functions to meet the demand of cities for ecosystem services.

Abstract

Forest soils provide vital ecosystem services such as filtering and allocating water, storing carbon, and providing habitat. However, changes to climate and increased requirements for the spaces that forests occupy for other land uses such as agriculture and urban development increases pressure on forest soils. This questions their ability to deliver ecosystem services in the future. This chapter reviews global forest soils, their microbiome, nutrient dynamics, indicators of sustainable forest management, how climate change will impact forests' ability to provide ecosystem services, and finally discusses impending pressures on forest soils.

Glossary

Microbiome The microorganisms in a particular environment.

Mineralization The process by which chemicals present in organic matter are decomposed or oxidized into easily available forms to plants.

Nitrogen fixation The chemical processes by which atmospheric nitrogen is assimilated into organic compounds, especially by certain microorganisms as part of the nitrogen cycle.

Phytobiome Plants, their environment, and their associated communities of organisms.

Weathering The process of wearing or being worn by long exposure to the atmosphere.

Key points

- Forests and forest soils provide ecosystem services including water filtration and carbon storage.
- Forests are under increased pressure from climate change and changes in land use which will affect soils and their capacity to supply ecosystem services.
- Soil properties are critical to forest resilience which is influenced by forest management activities.

Introduction

Why are forest soils and the forests that they support so important? Forests, and therefore forest soils, represent key ecosystems that are essential to life on Earth, support many aspects of nature, and provide society with a wide range of ecosystem services and benefits. The protection and maintenance of these services and benefits is fundamental to the natural world and to human well-being. The topic of forest soils is as broad as it is deep and includes, but is not limited to, the many aspects of soil biology, soil chemistry, and soil physical processes, effects of management, and understanding of natural processes that contribute to the wide variation in the world's forest soils.

The global distribution of forests, by climatic domain

**Fig. 1** The global distribution of forests by climatic zones.

Forests cover an area of 4.06 billion ha, representing approximately one third of the world's land surface area and are widely distributed, only excluding ice, snow, and rock covered areas. They are concentrated in five countries (Russian federation, Brazil, Canada, the United States, and China) that have 55% of the global forest cover. Tropical forests represent 45% of forest cover with 27, 10, and 11% occurring in Boreal, Temperate, and subtropical zones, respectively (Fig. 1). Of the total global area of forests, primary forests cover about 1.01 billion ha. These primary forests are characterized by low levels of human disturbance; they are dominated by natural processes, and consist of native species. The remaining forests are either regenerating or highly modified natural forests or are forests that have been planted and managed with a range of goals. Because of the wide and variable areas covered by forests, forest soils occur in many geographical locations around the world, creating an extraordinarily large potential for variation in the situations (forest types, geologies, and climate) in which the soils were formed. This has created a multitude of properties reflecting a correspondingly large diversity of topography, time scales, vegetation, and natural disturbance regimes together with the effects of human activity during the Holocene/Anthropocene. With increasing pressures from climate change impacts such as fire or invasive forest species, and increasing intensification of management, forest soils will continue to develop to express new properties with time.

Forest soils can be characterized as supporting potentially large, long-lived individual trees with deep root systems, substantial litter layers, and coarse woody debris. Forests represent a store of approximately 662 gigatons of carbon, of which 55% is stored in deadwood, litter, and soil organic matter (Food and Agriculture Organization, 2020). The deadwood and litter are important components of forest soils and provide important habitats for a wide range of forest animals, insects, and microorganisms. Forests also contain communities of understorey species, a wide diversity of soil dwelling organisms, including what is now widely termed as the soil microbiome (fungi, bacteria, amoeba, and Oomycetes), which through their activities, also cycle carbon and nutrients into and through forest soils. Key forest ecosystem processes of litterfall, carbon, and nutrient cycling are essential to maintaining productivity and these processes depend on this wide range in biodiversity to drive forest growth.

Forests and the forest soils that support them are widely seen as key to global sustainability now and into the future (World Business Council for Sustainable Development, 2015). The WBCSD suggested that the world needs more forests to meet current and future expectations for wood products, and for environmental services and benefits from forests. The WBCSD highlighted that up to 300% more fiber is required to meet the expected global shortage, which anticipates that the annual demand for wood will triple by 2050 to more than 10 billion m³ year⁻¹. This increased demand is attributed to population growth, rise of the middle class, and changing demands, for example, bioenergy and biofuels, and the rise of the bioeconomy. In addition to these increased demands, forests currently directly affect the livelihoods of 20% of the world's population, provide approximately 75% of clean freshwater, and support 9% of the world's primary energy demands while removing and storing vast quantities of carbon dioxide. Forests also support habitat for many important species with approximately 80% of terrestrial biodiversity found in forests (World Business Council for Sustainable Development, 2015). This importance of forests highlights just how fundamental forest soils are to so much of what forests provide. In terms of global efforts to stem climate change and the associated impacts, forests are seen as one of a few mechanisms that can have an effective impact in the relevant time frames, again further highlighting why forest soils are so important.

Human use of forests and forest soils

Forests have been a key source of timber and non-timber products for many generations. As civilization has developed, forests have been cleared to provide land for buildings, towns, cities, and agriculture. Out of this period of liquidation of old growth forests, forest management practices have emerged that have allowed for the protection and conservation of old growth forests and the emergence of intensively managed planted forests that now supply much of the world's supply of timber products. As a result, a wide range of forest types have been recognized with the key distinction between natural and planted forests (Table 1).

In the absence of harvesting for timber, trees in natural forests can be long-lived, and there are many examples of forest ecosystems around the world that contain populations of trees that are many hundreds or thousands of years old. Natural forests can, and in many cases, have sometimes undergone numerous natural disturbances such as fire, wind, earthquakes, disease, or insect attack. These disturbances can result in tree death, toppling of stems and tipping over of root plates, creating large amounts of coarse woody material. Large scale disturbance of forest can result in significant soil disturbance which will have implications for the ongoing development of the forest soil. The soil horizons can be mixed through the action of root plates tipping over or with potentially large amounts of organic matter buried beneath landslides. In particular, wind throws often create what is known as pit and mound topography, and freshly exposed mineral soils can become rapidly weathered. The mounds also act as elevated sites for seedling establishment and regeneration. In areas of the world where it occurs, volcanic disturbance, such as eruptions, can have a profound effect on forest soils. Volcanic eruptions can generate large amounts of heat, which can bake the soil and make it unsuitable for plant growth. Lava flows from an eruption can destroy the rooting systems of trees, making it difficult for them to recover. The loss of trees can also cause changes in soil hydrology, leading to increased erosion and runoff. In the long term, forests typically recover from these disturbances, but the process can take many years. After an eruption, the ash and other debris can blanket the ground, smothering vegetation and altering the soil structure and restricting infiltration. Ash deposits can lead to changes in the soil composition and nutrient availability, which in turn can affect the types of forest vegetation that can grow in the area. Since the last glaciation, there have been several generations of forests and cycles of natural disturbances with ensuing cycles of soil development and renewal as forests regenerate and stand dynamics alter the structure of the forests with time.

Planted forests managed for production of timber can also undergo these same disturbances, but the predominant disturbance occurs at the time of harvesting where there is potential for soil disturbance and modification during harvesting and stand replacement activities. Through time, a range of harvesting systems has been used to extract timber. These systems have become more intensive, as old growth forests were cleared for timber and to make way for expanding agricultural and urban land uses. Early on it was recognized that timber supply from old growth forests would not last forever. Therefore, in many places around the world,

Table 1 Example of FAO classification criteria for different types of natural and planted forests.

Natural forest		Planted forest				Non-forest
Primary	Modified natural forests	Semi-natural forests		Plantations		Trees outside forest (TOF)
		Assisted natural regeneration	Planted component	Protective	Productive	
						
Forest of native species, with no clearly visible indications of human activities and the ecological processes are not significantly disturbed.	Forest of naturally regenerated native species with clearly visible indications of human activities.	Silvicultural practices for intensive management (weeding, fertilizing, thinning, selective logging).	Forest of native species, established through planting, seeding or coppice of planted trees.	Forest of native or introduced species, established through planting or seeding mainly for provision of services.	Forest of introduced or native species established through planting or seeding mainly for production of wood or non-wood goods.	Stands smaller than 0.5 ha; trees in agricultural land (agroforestry systems, shelterbelts, orchards); trees in urban environments; and scattered along roads and in landscapes.

Adapted from Food and Agriculture Organization (2020) *Global Forest Resources Assessment 2020 Term and Definitions*. Roma: FAO.

plantations of timber producing species were established on previously forested lands, sometimes with introduced exotic species or with local indigenous species. There are 292 million ha of planted forests. Of these planted forests 131 million ha are considered to be plantations with more than 50 million ha of these managed intensively. Globally, 44% of plantation forests are planted with introduced species, primarily with members of two key genera, *Pinus* and *Eucalyptus*. These species are fast growing and provide timber that is suitable for many industrial purposes. The implications of these intensively managed forests for soil development beneath them is unknown, especially when the effects of management activities such as harvesting, site preparation, and stand management are considered.

Intensive management includes the use of herbicides, fertilizers, and thinning and pruning of stems with the goal of increasing timber production. Practices such as thinning and pruning do return organic matter to the soil surface which then enters the carbon cycle, providing habitat and energy for a range of forest dwelling organisms. The use of chemicals such as herbicides and fertilizers can have a variety of effects on plant nutrient and carbon cycling, although their use is confined to certain times during the life of the forests. These practices can result in shorter rotations, increasing the consequences of forest harvesting for soil disturbance. If done poorly, the use of heavy harvesting machinery can result in compaction and or mixing of soil horizons. However, most harvesting operations are regulated to avoid harvesting when conditions could result in soil damage, and to ensure practices such as brush mats consisting of non-merchantable stems, branches, and tree-tops, can be used to mitigate machine induced disturbance on harvesting trails. Other harvesting systems, such as continuous cover (the practice of maintaining a continuous canopy while removing selected trees), are also used to minimize disturbance to the forest and soils, particularly on slopes that are prone to erosion. Other harvesting practices include single tree or group selection or small coupe harvesting, which aim to minimize harvesting impacts on the forest and soils. Clear cutting of large coupes is still widely used in commercial plantations and can be highly mechanized, allowing for whole tree harvesting which can result in removal of not just the stems, but tree-tops, branches, and needles and leaves from the forest to log processing sites located on road edges. The processing of logs at the stump with suitable harvesting heads minimizes the loss of nutrients and returns the nutrient rich needles and leaves to the site together with the branches and treetops. The harvesting of trees for timber also presents the opportunity to use harvesting residues for energy purposes.

Natural disturbances to forest soils are usually more intense and occur over a shorter duration than those caused by forest management activities. In addition, natural disturbances typically affect a larger area of the forest and are less selective in terms of the plants and animals that are affected. As a result, natural disturbances can have a more profound impact on the structure and function of forest soils.

Intensive management of forest and forest soils

Wood has been widely used as a source of energy for cooking and heating since early civilizations. The use of wood for these purposes is still very common today and there has been widespread interest for many years in using wood to produce heat or steam, or steam for generating electricity, or as a feed stock for liquid biofuels or other biochemicals. Interest in using woody biomass for bioenergy has continued to grow since the first oil shocks in the 1970s. These shocks spiked an interest in alternative sources of energy, and now in modern times when concerns are fueled by efforts to reduce emissions from fossil fuels, the use of woody biomass for producing wood pellets for heating or biofuels for the road, marine, and aviation transport sectors is receiving more attention than ever. Biomass harvesting has increased, through the use of harvest residues from conventional harvested stands. More recently, purpose grown short rotation stands of fast-growing species such as willows have been established and managed for biomass crops. Another practice that has emerged with the harvesting of forest residues is the practice of stump harvesting. This is where the whole stump and as much of the root systems as possible is extracted and ultimately processed into bioenergy. This is not widely practiced as it is seen as resulting in considerable soil disturbance and greater loss of site nutrients.

The removal of harvest residues and the nutrients and carbon they contain was identified as an area of concern e.g., [Weetman and Webber \(1972\)](#) early on. In response, forest and soil scientists in many countries set up experiments in the late 1980s and early 1990s to examine the long-term impacts of intensive harvesting practices that involved the removal of harvest residues from conventionally harvested stands (stem only harvesting vs. whole tree harvesting). There has been much debate and scientific research about the sustainability of this practice and more recently about the climate effects of bioenergy ([Cowie et al., 2021](#)).

Most of the trials in planted forests have only examined the impact of the intensity of removal of harvesting residue at the end of one rotation; therefore, the question remains as to what might happen to plant nutrient resources at the end of subsequent rotations. Will nutrient removals be offset through atmospheric inputs or weathering of parent materials? This issue will gain more attention in the coming years as an increasing proportion of the current planted forest estate undergoes its second or third rotation. As the world tackles the goal of zero emissions and reductions in the availability and use of fossil fuels, the benefits of bioenergy production from forest residues are likely to increase, with uncertain consequences for forest soils. The findings generated by earlier research can be used to address issues arising around the sustainability of biomass harvesting (e.g., [Vance et al. \(2014\)](#)) and could prove useful in underpinning any development of local guidelines (e.g., [Titus et al. \(2021\)](#)) to support the use of forest residues for bioenergy or feedstocks for tree based biorefineries.

In some cases, the results provide confidence that not only is the productive capacity of most sites unlikely to be impacted after one rotation, but they also suggest that the future security of forest carbon pools and sequestration capacity will also be maintained in many situations. Care will have to be taken in situations where natural soil fertility is poor or where soil physical properties will not tolerate frequent disturbance during harvesting. Regardless of what the early results will have shown, it will be important to

continue this line of research because there will be an increasing area of planted forests entering their third or fourth rotations, where rotations are short and demand for harvest residues is likely to increase.

In addition to fertilizer application to replace nutrients removed during harvesting, strategies to ameliorate nutrient removals, particularly nitrogen, may include the use of nitrogen-fixing plants during periods of increased nutrient demand until canopy closure. There are numerous examples of suitable nitrogen-fixing species being sown into forest stands, and the occurrence of naturally occurring nitrogen-fixing species which can be considered weeds because of their competitive interactions with trees.

Other practices have also evolved to replace nutrients removed during harvesting and involve the use of common waste streams, for example, municipal wastewater treatment plant sludges commonly known as biosolids. Biosolids contain both carbon and nutrients, and their application to forest soils is seen as minimizing their negative consequences because forests are separate from the human food chain. The application of biosolids can benefit tree growth, especially where the forests are intensively managed, for example, where harvest residues are removed. However, concerns are still raised about possible organic and inorganic contaminants in biosolids. Therefore, it is essential that application programs are closely monitored to reduce the potential for any unintended consequences to arise.

Effluents from municipal wastewater treatment plants can also be applied to forests. One waste stream arising from the use of biomass is wood ash. Ash is rich in cations and is seen as a good way to replace the nutrients removed in the wood and bark of trees.

The planting and growth of forests together with the development of carbon and nutrient cycles have also been widely used to rehabilitate soils at the landscape level, particularly in the case of open cast mining. Once established on the reclaimed soils, trees provide protection to the soil surface and the production of litter returns carbon and nutrients to the soil. The growing trees provide habitats to a wide range of forest animals and insects, and the accumulating litter layer provides resources and habitat for more insects and animals.

Microbiome: Roots and mycorrhizae

Mycorrhizae have long been recognized as fundamentally important to the success of plant life. Mycorrhizal fungi can be found in association with the fine roots typical of tree root systems throughout the soil, wherever roots extend to. There are two key types of mycorrhiza common to most trees. These are endo or ecto mycorrhizae. The initial understanding of the importance of fungi in forest soils has now been extended to include the bacteria in forest soils found close to roots. Overall, the microbial communities consisting of fungi and bacteria found close to roots are known as the root microbiome and is part of the plant phytobiome. Through modern molecular tools and ecological principles, new understanding of the functions of the root microbiome has emerged. Previously, the understanding of the role of bacteria in forest soils was limited to functions, for example, nitrogen fixation and nitrogen cycling. Of far greater importance now is the idea of a forest wide web and the interconnectedness of trees through the microbiome, building on the concept of Darwin's 'root-brain hypothesis' and plant responses to environmental signals. This is a fast-moving area of research that is more than likely to impact greatly on our understanding of forest soils and the interactions between trees and microbes. This is similar to our understanding of the communication between the human gut microbiome and human brain that is redefining our understanding of human health and well-being. Managing the tree root microbiome or engineering the rhizosphere is considered to offer ways to increase forest health, productivity, and resilience under climate change.

Organic matter recycling in forests: Litterfall and the forest floor

Forests cycle carbon, nutrients, and water between the soil, atmosphere, and trees. Trees create sugars to support their growth by absorbing carbon dioxide and water during photosynthesis. Organic matter is deposited on the forest floor as leaves, twigs, and branches, and forests also add organic matter to soil through fine root turnover and decomposition of microbial biomass. This organic matter is decomposed by bacteria, fungi, and other soil organisms that releases nutrients that were locked in organic matter via mineralization, making them available for uptake by trees and other plants (Krishna and Mohan, 2017). This cycle of nutrient uptake and release helps to maintain fertile soil, preserve a healthy forest ecosystem, and allows forest soils to supply trees in forests with up to 60% of their nutritional requirements.

The development of a litter layer on the forest floor differentiates forest soils from those in other ecosystems such as grasslands. However, not all forests develop a distinct litter layer. Litter layers may not develop in forests where rates of litterfall are low, decomposition rates outpace deposition of litter which occurs in some tropical systems, or where accumulated litter is regularly removed or burned. Surface soils in forests are characterized by high organic matter content resulting from litter decomposition. However, it is not always possible to delineate a distinct organic layer from the underlying mineral soil, if, for example, management practices mix topsoil into the subsurface during harvesting or if the soil profile has been disturbed by animals.

Soil organic matter is a critical component of soil quality; it improves forest productivity by enhancing nutrient and water availability. It also plays an important role in soil structure by contributing to aggregate formation, increasing soil particle surface area which enhances water absorption, and by leading to the production of humic substances (humins, humic acids, and fulvic acids). These compounds are unlikely to be further decomposed due to their chemical structure (Berg and McClaugherty, 2020). Humus found on the forest floor shows distinct development and properties in different types of forests (Fig. 2).

Trees, particularly in boreal forests, have been shown to access free amino acids through their mycorrhizal associations, which has led to the development of organic nitrogen fertilizer that can be used instead of traditional mineral nitrogen fertilizer.

Fig. 2 Litter on the forest floor decomposes into simpler organic components. Humification breaks down plant debris leading to the formation of different types of humus under different forest types. Mor humus develops under coniferous forests under cool, wet climate conditions, where the breakdown of organic material is slow due to the low abundance of soil biota. This type of humus is characterized by a matted litter layer and an abrupt boundary between mineral soil and organic soil. Mull humus develops under deciduous forests where base-rich plant litter is actively broken down by abundant soil biota. It is characterized by a thin or absent litter layer, and a horizon of organic-enriched mineral soil. Moder is the intermediate between mull and mor types. This has a loosely structured litter layer and gradual boundary between mineral and organic layers.

Forest management practices that influence soil organic carbon		Afforestation and conversion of primary forests	Harvesting and harvest residue management
		Biomass removal and fire management	Nitrogen fertilizer addition and N-fixing species
Stand density and thinning	Tree species selection and diversity		
		Soil disruption and compaction from site preparation	Herbivory regulation

Fig. 3 Many forest management practices can increase or decrease forest soil organic stock.

Forest management activities can increase or decrease a soil's organic matter content, depending on the nature of the activities (Fig. 3). Examples of forest management practices that can increase soil organic matter include afforestation and adding nitrogen as fertilizer. Other management practices, including harvesting and removing harvest residue, generally have a negative impact on forest soil organic matter content because they remove the litter and wood that fuels decomposition and therefore nutrient cycling in forest soils (Mayer et al., 2020).

Global carbon dynamics and greenhouse gases

Forest soils are important for regulating atmospheric carbon dioxide levels and play a significant role in the global carbon cycle. Trees and other vegetation absorb carbon dioxide from the atmosphere through photosynthesis and store it in their leaves, stems, and roots. When leaves and other organic matter fall to the forest floor and decompose, they release carbon dioxide back into the atmosphere through respiration. Carbon is also transferred from trees to soil by rhizodeposition, which is the process whereby plants secrete organic matter and nutrients into the soil through their roots. Rhizodeposition can stimulate microbial activity in the

soil, which can lead to increased decomposition of organic matter and greater nutrient release, and has been shown to increase soil organic matter, improve soil structure, and increase soil water holding capacity. The net balance of the amount of carbon that is stored in forests, and the rate at which it is released as carbon dioxide, can have a significant impact on global climate change. Because forests cover a substantial area of the world's land surface, small changes to forest coverage can have substantial impacts on global carbon dynamics.

Forests mitigate greenhouse gas emissions by sequestering carbon and storing it for long periods of time. Carbon dioxide absorbed by trees is stored long-term in the trees themselves and the wood-based products they are used to produce, and as organic matter in forest soil (Pan et al., 2011). Globally, forest soils store 163 t ha^{-1} of carbon as organic matter, or 45% of all carbon in forests, suggesting soils have the potential to play a major role in mitigating climate change (Food and Agriculture Organization, 2020b).

There are many factors that contribute to the role of forest soils in global carbon dynamics. For example, the type of trees in a forest can affect the amount of carbon that can be stored in soils. Trees with deep roots tend to store more carbon in their soils than trees with shallow roots. Likewise, older forests tend to have more carbon stored in their soils than younger forests. Forest management, climate change-induced disturbances, and human activities can also impact the carbon storage capacity of forest soils. For example, by reducing or eliminating organic matter inputs from trees to soils, deforestation can lead to a decrease in the amount of carbon that is stored in soils, and forest fires can release large amounts of carbon into the atmosphere (Mayer et al., 2020).

Carbon stored in forest soils may help to offset other greenhouse gases such as methane and nitrous oxide. Forest soils can function as net sources or sinks of methane and nitrous oxide which are potent greenhouse gases that contribute to climate change. Methane is produced in soils by methanogenic microorganisms under oxygen depleted conditions which leads to methane emissions from soils. However, methane is also consumed by methanotrophic microorganisms in the presence of oxygen, which leads to the soil taking up more methane than they produce. Most forests situated on unsaturated soils are net sinks of methane. There is some evidence, however, that suggests net uptake of methane by forest soils is declining, especially at latitudes between 0 and 60°. This is due to changes in precipitation patterns and soil hydrological fluxes that reduce methane diffusion from the atmosphere into the soil which inhibits methane uptake by methanotrophic soil microorganisms (Ni and Groffman, 2018). Nitrous oxide is produced in soils by biological activity or chemical reactions. The majority of nitrous oxide emitted from soil is produced during biological denitrification in low oxygen conditions when carbon and nitrate are available (Zhu et al., 2013). Nitrous oxide is an intermediate product of denitrification, whereas complete denitrification produces nitrogen gas, a natural and abundant constituent of the atmosphere. In oxygen depleted soils, complete denitrification outpaces incomplete denitrification. Soils can become net sinks for nitrous oxide as uptake occurs. In forest soils with low levels of nitrate and forest floors with high C:N ratios, we can generally expect forest soils to be net sinks for nitrous oxide. However, it is unclear whether global forest soils are net sources or sinks of nitrous oxide because conditions are highly variable and other biological processes such as nitrifier denitrification can produce and take up nitrous oxide (Chapuis-Lardy et al., 2007).

Forest management practices have a significant impact on emissions of carbon dioxide and other greenhouse gases from soils. Soil carbon dioxide emissions can be up to 10 times higher in managed forests than in unmanaged forests. This can be partly attributed to soil disturbance that occurs during forest management. Clearcutting and replanting disturbs the soil and can release carbon dioxide and other greenhouse gases that were previously trapped in the soil. It also alters the soil conditions, thereby affecting nitrous oxide and methane fluxes. For example, removing large swaths of trees in boreal regions suddenly eliminates tree water uptake, and this could elevate local water tables leading to wetter soils that are more enabling to nitrous oxide and methane production. In contrast, by removing only certain trees, selective logging can decrease nitrous oxide and methane emissions from soils. This is because the remaining trees create a microclimate that is more conducive to aerobic soil conditions, thereby preventing conditions that enhance production of nitrous oxide and methane.

Watershed nutrient dynamics and hydrology

Forests regulate water quantity and quality in many regions around the world. Changes in forest cover alter the supply of water resources by influencing precipitation patterns, drinking water supply and quality, flood control, stream flows, and recreational activities (Holmes et al., 2017). Forested watersheds supply a large proportion of the world's accessible fresh water for domestic, agricultural, industrial, and ecological needs in both upstream and downstream areas (Food and Agriculture Organization, 2013).

Forest soil conditions and properties strongly influence how much water is stored in soil, how quickly water moves through the soil matrix, and how quickly water moves from soil to surrounding surface or groundwater sources, to plants, and back to the atmosphere (Black, 1996). Forested soils have unique characteristics that affect their ability to hold and transport water. Unlike most other ecosystems, forest soils receive large inputs of leaf litter and woody debris, and decomposition of this litter contributes to the development of soils with a large content of organic matter, and in many non-tropical forests, a litter layer. Large organic matter content in soils and forest litter layers are both associated with large pore spaces, which contribute to infiltration rates that often exceed rainfall intensity. As a result of these characteristics, forest soils have high water storage capacity, and the presence of a litter layer both holds water and creates a physical barrier that reduces water loss from soil as evaporation (Edwards et al., 2015).

Soil hydrology and biogeochemistry are intimately linked in forested watersheds (Fig. 4). Forested watersheds improve water quality and enhance water storage; however, forest management affects nutrient cycling, water transport, and surface and groundwater quality and quantity. Management activities such as road construction, harvesting, site preparation for regeneration, and

Fig. 4 Water and biogeochemical cycling in forests are tightly linked. Left (A) shows a simplified representation of water cycling in forests while right (B) shows a simplified representation of carbon cycling.

fertilization are all linked to reduced water quality in forested watersheds. These activities cause changes to sediment loads, stream temperature, dissolved oxygen, and dissolved nutrients.

Nitrogen is the primary nutrient that limits tree growth, but boron and other micronutrients can also reduce forest productivity. Many studies linking soil hydrology and biogeochemistry in watersheds have focused on nitrogen, partly because of its effect on productivity, but also because nitrogen in the form of nitrate is a pollutant in surface and groundwater. Nitrate leaching from forest soils to water sources can be a problem in some circumstances, for example, following harvesting when nitrogen uptake by trees is reduced, when planting new forests on poor quality soils that require the addition of nitrogen fertilizer, or when planting forests on land with a history of animal grazing and agricultural fertilizer use because nitrogen concentrations may already exceed tree requirements. There is also a risk of phosphorus loss in sediments following harvesting disturbance in the absence of best practices such as lack of riparian areas.

Soil and forest resilience

Resilience refers to a forest's capacity to withstand and recover from change and disturbance. The concept is usually associated with plant recovery, which is determined by easily measured metrics such as tree growth, reproduction, abundance, canopy cover, species diversity, and biomass. Forests are under increased pressure from climate change and disturbance from wildfires, insect attacks, and storms. Biotic and abiotic soil characteristics are critical to the survival and recovery of trees following such events (Ibanez et al., 2019).

Forest resilience relies on reciprocal relationships between trees and soils. Reductions in forest canopy cover or stand density will reduce organic matter inputs from litter and woody detritus, which can, in turn, reduce forest soil organic matter content, thereby decreasing soil water holding capacity, altering nutrient availability and transport, and modifying soil ecology. Thus, these changes in tree canopy or stand density will influence how soil conditions respond to changes in temperature, solar radiation, and water inputs, thereby altering a soil's capacity to support forest growth.

Climate change can affect soils in several ways, and these changes can impact forest resilience. Increased intensity and frequency of droughts will lead to more soil erosion and degradation. By reducing soil water content, droughts are also associated with increased soil temperatures; wet soils have a greater specific heat capacity requiring more energy to change their temperature, and therefore, wet soils have a greater ability to regulate temperature changes. Warmer soil temperatures can stress trees and increase tree mortality. Changes in precipitation patterns can affect the amount and timing of available water in soils, which can affect their ability to support forest growth. Soils that have experienced wildfire are often more susceptible to erosion, which can lead to the loss of soil and plant nutrients. This makes them susceptible to the development of hydrophobic conditions, reduced infiltration, and increased runoff as a result of wildfire burning off soil organic matter. They also have increased susceptibility to flooding and encroachment by invasive species. Overall, the effects of reduced tree growth, and more frequent droughts and fires, can lead to a cycle of ecosystem and soil degradation, which will reduce forest soil health and the resilience of forests to these disturbances.

By disrupting and altering the flow of energy and nutrients between soils and trees, climate change-induced disturbances can alter a soil's capacity to support tree growth thereby affecting organic matter inputs from trees to soil. Soils with a large organic matter content and good structure provide habitat to support healthy populations of soil organisms that cycle nutrients and organic matter and help to protect soils from erosion. Fertile soils that are protected from erosion are better able to recover from disturbances such as insect attacks. While disturbances such as insects can cause significant damage to trees, if the soils are healthy, the trees are more likely to survive and recover.

Forest management activities can influence the capacity of soils to support forest regeneration following harvest. Harvesting can interrupt energy, water, and nutrient flows between the soil and trees. However, whether such interruptions result in changes to long-term forest ecosystem functions will depend on many factors; steep slopes, shallow soils, limited nutrient supplies, and

absence of vegetation reduce the ability of a forest to recover following disturbance (Ibanez et al., 2019). The type of harvest activities will also affect forest soil conditions. Selective harvesting of natural forests only removes one or a small number of trees leaving the rest of the stand intact, thereby minimizing the effects on soil and the rest of the forest. However, clearcut harvesting of natural forests removes all trees, and removing the canopy creates soil conditions similar to those that occur following natural disasters which can severely reduce forest resilience. Harvesting machinery can influence physical soil properties which can hinder seedling establishment after harvest. Soils that have been damaged or compacted by heavy equipment are less able to support forest regeneration and tree growth.

Sustainable forest management: Criteria for indicators

Since 1990, an estimated 420 million ha of forests have been cleared for other land uses, including the production of timber. Loss of forests also means that the soils beneath the forests are subject to the influence of different land uses. Soils under either agricultural or urban land uses are no longer considered forest soils although their properties reflect this previous land use.

Since 1990, afforestation has reduced the net loss of forests; planting trees on non-forested land has reduced net losses of forests by 178 million hectares. Afforestation of agricultural land or degraded lands is widely seen around the world and in some cases, large gains in productivity have been observed on previous agricultural land (e.g., Beets et al. (2019)) due to the legacy of fertilizer inputs.

The trends of increasing deforestation and the potential negative impacts of poor management practices have seen the evolution of local, national, and international systems for monitoring and reporting on sustainable forest management practices, including the protection of forest soils and their productive capacity. Today, in response to these concerns, certification schemes have emerged for forests managed for timber products, and now 13% of global forest cover is covered by the Programme for the Endorsement of Forest Certification (300 million ha (Programme for the Endorsement of Forest Certification, 2021)), while 228 million ha of forests are covered by the Forest Stewardship Council Certification Scheme (Forest Stewardship Council, 2021). At the national level, many countries report the state of their forests and forest management through the Montreal Process for Sustainable Forest Management. This process has established a set of key criteria and indicators of sustainable forest management which are reported on regularly at the national level. This has allowed for trends in the criteria and indicators to be assessed at a global level and includes the state of forest soils. More recently, the United Nations Sustainable Development Goals have emerged and are relevant to the management of forest soils and the contribution they make to nature and human well-being (Fig. 5).

Soil quality underpins the productive capacity of forests which provide important ecosystem services and benefits. The quality of forest soils has been of interest for some time (Schoenholtz et al., 2000) because of the relationship of many soil quality indicators with forest productivity, which has been the focus of many studies. Amongst important soil quality indicators are nitrogen, phosphorus, C:N ratio, soil bulk density as well as total soil porosity. These have generally been applied to surface mineral soils and do not consider the organic horizons, which are an important feature of forest soils. They also do not consider deeper soils or processes not seen as directly important to plant growth. For example, the weathering of rock fragments within the root zone of trees and parent materials deeper in soils are not considered, but are areas where research could help to improve our understanding on the sustainability of managed forest soils. Remote sensing, geospatial techniques, and mapping technologies are providing useful insight into the nature of forests, and fusion of this new knowledge about forests with new sensing technologies applied to forest soils will increase our understanding about the evolving nature of forest soils.

Fig. 5 Goal 15 of the United Nations Sustainable Development Goals (SDGs) is Life on Land. The SDGs are related to one another, with the thicker lines and proximity to goal 15 representing other SDGs that are more closely related to goal 15.

Modern molecular tools have been applied to forest soils for several years, but more recently cheaper, high throughput analytical systems have provided an explosion of new understanding of forest soil microbial ecology. Further advances in the study of eDNA (Ruppert et al., 2019) will allow for an even greater understanding of the diversity of life in forest soils and how this varies between major forest types and with management. There is a current focus on what is now known as the forest microbiome and what this consists of, and the role it plays in the health and productivity of forests.

Soils in urban forests

The term urban soil describes soils located in urban areas that have been affected by human activities such as construction, pollution, and changes to the natural landscape, including the planting of trees. Forests and trees found in urban areas provide benefits to the environment and human health including reducing air pollution, providing shade, and improving mental health. Some soil classification systems already recognize urban soils as a distinct soil class with identifiable characteristics, and urban soils are becoming increasingly important as more than half of the world's human population live in urban areas. Some characteristics of urban soils may impede tree growth. For example, urban soils are often compacted by foot traffic and construction activity, which can limit oxygen availability to tree roots and inhibit water and nutrient infiltration and transport to tree roots. Urban soils often have a higher pH than other forest soils due to the presence of concrete and other building materials. Urban soils also tend to have higher concentrations of 'heavy' metals and other pollutants due to runoff from roads and buildings (Scharenbroch et al., 2005).

Like other forest soils, urban soils that are forested can sequester carbon and there is some evidence that this can be related to tree species. Relative to natural and production forests, less is known about nutrient cycling and carbon content of urban forest soils. Tree species vary in their litter quality, and also in their rates of litter decomposition (Binkley and Giardina, 1998). Research suggests that these differences contribute to differences in soil organic carbon content in urban soils, with greater soil organic carbon in urban forests planted with coniferous species than in urban forests planted with broadleaved species (Xu et al., 2021).

Future pressures and requirements for forest soils

There are several interrelated challenges ahead for forest soils. First, world population is likely to be close to 9.8 billion by 2050, creating future global demand for the provision of wood and fiber products, in the order of 10 billion m³ year⁻¹. This will require either larger areas of forests to be harvested, or greater productivity from existing forests. At the same time, the results of global efforts to keep global temperature rise below 2 degrees Celsius will be apparent, therefore, the challenge for forests and forest soils is how they can continue to be key carbon sinks and reservoirs that contribute to meeting the Paris Agreement targets while simultaneously providing the wood and fiber resources for traditional uses and meet new demands for biomass resources to replace fossil carbon derived products. At the same time, it is also expected that there will be greater disturbance from climate related events, for example, wildfires, extreme winds and floods, disease, and pest outbreaks that will result in loss of forests. This will jeopardize their ability to contribute to efforts to meet the Paris Agreement targets to provide timber resources, and at the same time put more pressure on remaining forests (Fig. 6). Whether or not there will be increasing pressure to clear more forests to meet demand for land from the growing population remains to be seen, given current trends to intensify agricultural production together with new trends in addressing demands for protein. Increasing population density in existing urban areas may offset the need to clear forested land, but on the other hand the need to move climate threatened communities might result in more loss of forests. To meet these interrelated challenges, it will be essential for the management and conservation of forests and forest soils to be a priority for future governments along with more collaboration internationally to secure these critical resources.

Summary and conclusions

Forest soils are as diverse as the forests they support but increasingly they will reflect the outcomes of many more years of human influences and homogenization of their properties. It will become even more important to maintain and enhance the productivity of our managed forests, given the reliance on forestry to reduce atmospheric carbon levels and substitute fossil fuels at the same time while protecting our remaining primary forests. This will require careful management of the soil resources ensuring that they can support increases in forest productivity while contributing to carbon sequestration and storage. Increasing global demand for timber products is creating more pressure on forests, and new management practices will need to be developed to buffer the soil resources against any pressures resulting from intensification (e.g., shorter rotations, higher stocked stands, more disturbance, and residue removal). However, new technologies promise the potential to avoid some negative impacts, such as robotic harvesting systems that protect the soil surface from disturbance while improving worker safety (Parker et al., 2016).

Acknowledgments

The authors wish to thank Serajis Salekin and Priscilla Lad for their comments and suggestions, and Loretta Garrett for the concept behind Fig. 5.

Fig. 6 This diagram shows how soil and other natural capital are important for management decisions in forestry. When trees are planted, they will interact with the natural capital including soils and the supporting processes such as nutrient cycling. Climate change will affect the natural capital and forest management decisions. Managing and protecting soil will impact ecosystem services under climate change and will future proof the planted forests through realizing the maximum benefits from planted forests. Moreover, it will give information to underpin licenses to operate.

Abstract

Agroforestry incorporates trees/shrubs into farming systems, and allows for the production of trees and crops or livestock from the same piece of land in order to obtain economic, ecological, environmental and social benefits. Climate-resilient land-use systems that promote biodiversity, nutrient cycling and sustainability as an adaptation strategy to enhance people's life globally are being promoted by several international organizations. In this context, agroforestry land-use systems create multifunctional landscapes contributing to climate-resilient processes and social well-being and therefore considered as the future of global land-use. This book chapter highlights such land-use systems supported by recent research outcomes.

Introduction

Agroforestry involves the deliberate growing of trees and shrubs with crops, sometimes with animals, in interacting combinations for a variety of objectives. Agroforestry farming practices have been used throughout the world for millennia but have only attracted scientific attention and attained prominence as relevant land-use practices since the late 1970s. Today, acting as an interface between agriculture and forestry, agroforestry is considered to be a promising and sustainable approach to land use. Improvement and utilization of multipurpose trees that produce food, fodder, timber, and fuelwood in integrated farming systems offer sustainable solutions to several serious land management issues such as food security, environmental protection, and climate change, in both developing countries and the industrialized world. In the former, agroforestry is largely aimed at food security, whereas in industrialized countries, agroforestry land-use systems are often recommended for environmental protection (biodiversity enhancement, non-point source pollution and soil erosion control, and the development of long-term and efficient nutrient cycling mechanisms). In addition, agroforestry systems (AFS) can provide micro-climatic modification for enhanced water-use efficiency, and climate-change mitigation (carbon sequestration, enhancement of climate resilience) as well as product diversification to promote on-farm economic viability. This chapter presents an account of the major forms of agroforestry systems in both tropical and temperate situations and their role and potential for addressing current and future land-management issues.

Emergence of agroforestry as a land-use approach

The practice of growing trees and crops has been prevalent for many centuries in different parts of the world, especially under subsistence farming conditions. For example, homegardens are reported to have been associated with fishing communities living in moist tropical regions around 10,000 BCE, and domestic animals were introduced into forests for foraging in Europe around 4000 BCE. However, it has only been since the late 1970s that these indigenous forms of growing trees and crops/animals together have come to be thought of as a truly scientific land-use scenario.

Several factors contributed to this development. During the mid-to-late 1900s, agriculture and forestry in the industrialized nations had been successfully transformed into commercial, single-commodity-production enterprises. When the newly independent nations of the developing world were faced with the problem of feeding their large populations during the 1950s and 1960s, policy makers thought that the best solution was to embrace the successful agricultural models common in the industrialized world. Several food-production technologies were subsequently developed with an emphasis on the production of preferred crop species in monocultural (sole-crop) stands with a heavy reliance on agrochemical inputs (fertilizers, insecticides, herbicides, etc.), mechanization, and irrigation. In the 1970s, these efforts, collectively called the Green Revolution, resulted in substantial gains in food production and helped avert large-scale hunger in some regions of the world. At that time, most of the international agricultural research centers (IARC's) of the Consultative Group on International Agricultural Research (CGIAR) system and national country programs focused on a few individual food crops and their production technologies for sole-crop production systems. Similar patterns of single-species stands of trees were also adopted in plantation forestry and fruit orchards in many parts of the tropics and that resulted in significant gains in wood and fruit production. However, many farmers, especially the poorer ones in the tropics and subtropics, were often cultivating their crops in mixed stands for more than one season, and were commonly nurturing trees in their cropping systems for a myriad of reasons. These traditional, mixed production systems of raising food crops, trees, and animals together, as well as exploiting a multiple range of products from natural woodlots did not fit into this "modern" single-commodity paradigm, and were ultimately discouraged.

Serious doubts began to be expressed after the advent of the Green Revolution, about the relevance of single-commodity strategies and the policies promoting them. In particular, there was concern that the basic needs of the poorest farmers were neither being considered nor adequately addressed. It soon became clear that many of the technology packages that contributed to the Green Revolution, such as irrigation systems, fertilizers, and pesticides, were not affordable by the poor farmer on the one hand, and in addition, their large-scale application had serious environmental consequences on the other. It was also recognized that most tropical soils, which are poorer and more easily degraded than temperate-zone soils, were unable to withstand the impact of high-input technologies. In addition, the disastrous consequences of increasing rates of deforestation in the world's tropical regions also became a matter of serious concern.

Faced with these problems, land-use experts and institutions intensified their search for appropriate strategies that would be socially acceptable, enhance the sustainability of the production base, and meet the need to produce multiple outputs. These collective efforts led to a critical investigation of the shunned and historical farming practices that utilized combinations of trees, crops, and livestock concurrently on the same land unit. The inherent advantages of traditional land-use practices involving trees – sustained yield, environmental conservation, and multiple outputs – were quickly recognized. Agroforestry thus began to come of age in the late 1970s and the establishment in Kenya in 1977 of the International Council for Research in Agroforestry (ICRAF) [www.icraf.cgiar.org], now known as the World Agroforestry Centre, signified the institutionalization of agroforestry and heralded the beginning of the era of agroforestry as a multidisciplinary science.

In the more industrialized regions, many of which are found in the temperate zone, the evolution of "modern" agroforestry was slower than in the tropics. J. Russell Smith's classical work "Tree Crops: A Permanent Agriculture" (Smith, 1950) is considered to have created a new wave of interest in agroforestry; he argued that "an agricultural economy based almost entirely upon annual crops such as corn and wheat is wasteful, destructive of soil fertility and illogical." In the temperate zone, adoptions of highly-technical agricultural practices and aspects of the green revolution have resulted in many environmental and social problems. This ultimately led to much increased research and practical activity in the development of sustainable farming systems and among the prominent disciplines and practices advocated, agroforestry land-use systems emerged as a viable alternative.

The value of temperate agroforestry systems has now been formally acknowledged, and many have been described for specific regions (e.g. Coleman et al., 2018). Many of these systems are common-sense adaptations of historical knowledge that exists on the benefits of incorporating trees into farming systems (see Smith, 1950), but many are new applications of systems that have been successful in other situations. Most modern textbooks on agroforestry confine discussion of temperate systems to individual chapters (Nair et al., 2021; Coleman et al., 2018; Nair and Garrity, 2012), although both research and descriptive information on temperate agroforestry is available for localized regions such as Canada, United Kingdom, Europe, China, Chile, Argentina and New Zealand (Coleman et al., 2018).

Agroforestry: Concepts and principles

Agroforestry is a loosely defined term. Several definitions – long and short – and associated descriptions were proposed for agroforestry during the 1980s and 1990s. However, a consensus has since emerged that agroforestry is one of the terms (including

agriculture, forestry, and several subsets within them) that cannot – and perhaps need not be – defined exactly, and that the concept is more important than the definition. Today, there is a general understanding that agroforestry refers to the purposeful growing of trees and crops in interacting combinations for a range of objectives including both a variety of products or commodities and a vast array of environmental and other ecological services. Basically, it involves the deliberate mixing of trees and shrubs – collectively called woody perennials or trees – on the same unit of land as agricultural crops or animals, either in some form of spatial arrangement or temporal sequence. In the resulting systems, there is significant ecological and economical interaction between the woody and the non-woody components. An agroforestry system will have more than one output, and its ecology and economics will be more complex than in a monocultural agricultural or forest system.

Four key “I” words are sometimes used to denote the essence of agroforestry: intentional, intensive, interactive (biophysical interactions between the perennial and annual components), and integrated (system components are integrated both temporally and spatially) (Garrett et al., 2022). The term “intentional” implies that systems are intentionally designed and managed as a whole unit, and “intensive” means that the systems are intensively managed for productive and protective benefits, although agroforestry based on unimproved (wild) trees is generally not considered intensive. It is often emphasized that all agroforestry systems are characterized by three basic sets of attributes: productivity (production of preferred commodities as well as productivity of land resources), sustainability (conservation of the production potential of the resource base), and adoptability (acceptance of the practice by the farming community or other targeted clientele). These different concepts are captured in ICRAF’s characterization of agroforestry as “a dynamic, ecologically sound system of natural resource management; by integrating trees on farms and in the agricultural landscape, it helps diversify and sustain production for enhanced economic, environmental and social benefits.”

As noted earlier, the motivation for agroforestry research differed between the tropical and the temperate regions. This is to be expected, given that the structure and management of land-use systems are determined not only by biological components, but also by site-specific ecological features and local social and cultural characteristics. This is true for all forms of land use, be it agriculture (including animal production) or forestry. These inescapable differences manifest themselves in the nature, characteristics, objectives, and expectations of agroforestry practices in the two broad geographical regions; nonetheless, agroforestry practices in both regions embrace the same concepts and principles.

In addition to agroforestry, several other terms ending with “forestry” became prominent in the 1970s and 1980s as a consequence of increasing global interest in tree planting activities. These would include terms such as community forestry, social forestry, and farm forestry. Although not defined precisely, these terms emphasize the participation of people in tree planting activities, not necessarily in association with agricultural crops and/or animals as in agroforestry, but with social objectives that rank equally in importance with production objectives. Social forestry refers to using trees and/or tree planting specifically to pursue social objectives, usually the betterment of the poor, through the delivery of the benefits of tree products and/or tree planting to the local people. Community forestry, a form of social forestry, refers to tree planting activities undertaken by a community on communal or so-called common lands; it is based on the direct participation of local inhabitants in the process, either by growing trees themselves, or by processing the tree products locally. Farm forestry, a term used mainly in Asia, refers to tree planting on farms. The major distinction between agroforestry and these other terms is that while agroforestry emphasizes the interactive association between woody perennials and agricultural crops and/or animals, the other terms refer solely to tree planting. Several other terms and initiatives such as permaculture, agroecology, and farming systems that encompass the concept of integrated land use (with or without trees, such as regenerative agriculture) have also emerged in the last several decades. In practice, however, all of these activities and practices that include trees directly or indirectly refer to growing and using trees to provide food, fuelwood, fodder, medicines, building materials, and cash income. Only blurred lines, if any at all, separate them, and they all embrace agroforestry concepts and technologies. Therefore, in common land-use parlance, these different terms are often used as synonyms, and sometimes out of context.

Agroforestry: Practices and systems

A wide range of traditional land-use systems that fit the concept of agroforestry have been identified from different parts of the world and many others being practiced may remain to be identified. The most organized effort to understand the complexity, diversity, and extent of indigenous agroforestry systems in the tropics was a global inventory undertaken by ICRAF between 1982 and 1987. That activity, aimed at systematically collecting, collating, and evaluating data pertaining to such systems around the tropics, assembled for the first time a substantial body of information on many AFS including their structure and function, and their merits and weaknesses. Based on this comprehensive database, a classification scheme for AFS was proposed based on several criteria:

1. The structure of the system, based on the nature and arrangement of the three major groups of components: a. agrisilviculture (trees/crops), b. silvopasture (trees/animals) and c. agrosilvopasture (trees/crops/animals).
2. The primary function of the system: a. production of basic needs (such as food, fodder, fuelwood and cash), and b. protection or service functions (such as soil fertility build-up, environmental amelioration, wind-protection, and erosion control)
3. Spatial arrangement of components, i.e. the time sequence of component arrangement: a. Simultaneous (trees intercropped with crops or livestock), or b. Sequential (trees and crops rotated in sequences).
4. Level of management: a. subsistence to commercial, or b. household consumption to market-oriented

Table 1 Major agroforestry practices in the tropics and the temperate regions.

Agroforestry practice	Brief description
Tropical agroforestry	Fast-growing, preferably leguminous, woody species grown in crop fields; the woody species pruned periodically at low height (<1.0 m) to reduce shading of crops; the prunings applied as mulch into the alleys as a source of organic matter and nutrients, or used as animal fodder.
Alley cropping (hedgerow intercropping)	
Homegardens	Intimate multistory combinations of a large number of various trees and crops in homesteads; livestock may or may not be present.
Improved fallow	Fast-growing, preferably leguminous, woody species planted and left to grow during fallow phases between cropping years for site improvement; woody species may yield economic products.
Multipurpose trees (MPTs) on farms and rangelands	Fruit trees and other MPTs scattered haphazardly or planted in some systematic arrangements in crop or animal production fields; trees provide fruits, fuelwood, fodder, timber, etc.
Silvopasture:	Integrating trees in animal production systems:
• Grazing systems	– Cattle grazing on pasture under widely spaced or scattered trees.
• Cut and carry system (Protein banks)	– Stall-feeding of animals with high-quality fodder from trees grown in blocks on farms.
Shaded perennial-crop systems	Growing shade-tolerant species such as cacao and coffee under or in between overstory shade-, timber-, or other commercial tree crops.
Shelterbelts and windbreaks	Use of trees to protect fields from wind damage, sea encroachment, floods, etc.
Taungya	Growing agricultural crops during the early stages of establishment of forestry (timber) plantations.
Temperate-zone agroforestry	Trees planted in single or grouped rows in herbaceous (agricultural or horticultural) crops in the wide alleys between the tree rows.
Alley cropping	
Forest farming	Utilizing forested areas for producing specialty crops that are sold for medicinal, ornamental, or culinary uses.
Riparian buffer strips	Strips of perennial vegetation (tree/shrub/grass) planted between croplands/pastures and streams, lakes, wetlands, ponds, etc.
Silvopasture	Combining trees with forage (pasture or hay) and livestock production.
Windbreaks	Row trees around farms and fields, planted and managed as part of crop or livestock operation to protect crops, animals, and soil from wind hazards.
Bioenergy	Short-rotation woody crops such as willow (<i>Salix</i> spp.), miscanthus (<i>Miscanthus</i> spp.) or switchgrass (<i>Panicum virgatum</i>), grown in conjunction with other on-farm agroforestry practices such as intercropping, or as a sole-crop

Source: Modified from Nair PKR, Gordon AM, and Mosquera-Losada MR (2008) Agroforestry. In: Jorgensen SE and Fath BD (eds.) Ecological Engineering. pp. 101–110. Oxford, U.K: Elsevier.

Other classification schemes of AFS have also been proposed, but essentially, they all are based upon the above criteria and concepts. Various characterizations and descriptions of AFS such as agrisilvicultural systems for fuelwood production in semiarid lands, silvopastoral systems for animal production on sloping lands, multistrata homegardens in humid tropics, etc., are common in the agroforestry literature. Moreover, descriptions of existing systems as well as recommendations concerning potential agroforestry technologies for specific agroecological zones include a mixture of various forms of agroforestry in terms of the nature and arrangement of components, and often, several AFS can be found within the same ecological regions. Thus, in general, any specific agroforestry practice cannot be identified exclusively with a specific ecological region, and vice versa.

A list of major global agroforestry practices is presented in Table 1. Local adaptations and manifestations of these (and other) practices exist as innumerable agroforestry systems with site-specific characteristics, especially in the tropics and subtropics. Compared with the tropics, agroforestry practices and systems in the temperate zone are less diverse and complex. The Association for Temperate Agroforestry (AFTA: www.aftaweb.org) has recognized five major agroforestry practices in North America: Alley cropping, forest farming, riparian buffer strips, silvopasture, and windbreaks. Other temperate-zone AFS include ancient tree-based agricultural systems involving a large number of multipurpose trees such as chestnuts (*Castanea* spp.), oaks (*Quercus* spp.), carob (*Ceratonia siliqua* L.), olive (*Olea europaea* L.), and figs (*Ficus* spp.) in the Mediterranean region. The dehesa system, grazing under oak trees with strong linkages to recurrent cereal cropping in rangelands, is also a very old European practice. In addition, bioenergy systems, where fast-growing woody perennials are grown in short-rotation within an agricultural context, would also qualify as an agroforestry system.

Distribution and area of agroforestry systems

The nature and intensity of the type of agroforestry practiced in a locality or region is determined primarily by its ecological potential and socioeconomic conditions. Humid lowlands and other tropical regions of the world that are not constrained by climatic limitations such as extreme temperatures and long dry seasons are home to a large diversity of plant species and therefore numerous and diverse agroforestry systems. Moreover, socioeconomic factors such as human population pressure, greater availability of labor, smaller land-holding size, complex land tenure, and lack of proximity to markets often support more and diverse agroforestry systems in such regions. In general, small family-farms, subsistence food crops, and emphasis on the role of trees in improving soil

quality of agricultural lands are characteristic of tropical agroforestry systems. On the other hand, environmental protection is the main motivation for agroforestry in temperate regions, where intensive, mechanized monocultural production systems of agriculture and forestry have contributed to reduced biodiversity and loss of forest resources and wildlife habitat, and increased environmental hazards such as erosion, non-point source pollution of ground water and rivers, and greenhouse-gas emissions.

As noted above, multistrata systems (homegardens, shaded perennial systems, and multilayer tree gardens) are common in tropical regions with high human population, while less intensive systems are common in areas with lower population density. In the moist tropical and dry regions, the nature of agroforestry systems is influenced by climate and population pressure: homegardens and multilayer tree gardens are found in the relatively wetter areas; tree intercropping systems such as multipurpose trees on croplands, silvopastoral (grazing) systems, and protective systems of windbreaks and shelterbelts are common in these regions. In the tropical montane regions that have favorable rainfall regimes, sloping lands and rolling topography make soil erosion an issue of major concern; consequently, soil conservation is one of the main objectives of agroforestry in these regions. Shaded perennial systems, the use of woody perennials in soil conservation, and silvopastoral systems are the major forms of agroforestry in such tropical highlands. Several other specific systems also exist in the tropics such as apiculture with trees, and aquaculture involving trees and shrubs; however, information on these systems was too meager to warrant their inclusion here.

Estimating the area under AFS on a farm itself is challenging because of the lack of clarity and proper procedures for delineating the area influenced by trees in a mixed stand of trees and crops (Nair et al., 2009). In simultaneous systems, the entire area occupied by multistrata systems such as homegardens and shaded perennial systems and intensive tree-intercropping situations can be listed as agroforestry. However, most AFS are rather extensive, where the components, especially trees, are not planted at regular spacing or density such as in parkland systems and extensive silvopastures. Such situations exist also in Europe and other temperate regions where the mosaics of intensive field systems, with hedgerows and patches of woodland are common features of agricultural landscapes. The problem of estimating the area under agroforestry is more difficult in the case of practices such as windbreaks and boundary planting where the trees are planted at wide distances between rows (windbreaks) or around agricultural or pastoral parcels (boundary planting), because the influence of trees both above and below ground extends beyond the obviously visible area of trees. For windbreaks, the rule of thumb is that the area protected from wind erosion extends laterally to 10 times the height of trees in the central core of windbreaks. The problem has a different dimension of difficulty when it comes to sequential tropical systems such as improved fallows and shifting cultivation. In such situations, the beneficial effect of trees and other woody vegetation (in the fallow phase) on the crops that follow them (in the cropping phase) is believed to last for a variable length of time (years). Despite these temporal and spatial issues, a recent ICRAF survey (www.worldagroforestry.org/advanced-search?search_api_fulltext=high-resolution+remote-sensing+) using high-resolution remote-sensing quantified the areas of agricultural landscapes with at least 10% tree cover worldwide as nearly a billion hectares. Considering the prevalence of agroforestry practices in non-agricultural lands, the area currently under agroforestry is estimated to be 1.6 billion ha globally (Table 1).

Brief description of major agroforestry systems

Intercropping (alley cropping and other forms of tree intercropping)

In the tropics, alley cropping was developed by researchers in the 1970s and 1980s in an attempt to find alternatives to the long-term fallows of shifting cultivation. The main motivation and rationale for alley cropping was the perceived soil-improving potential of fast-growing, leguminous woody species and their ability to withstand repeated cutting. It was hypothesized that by integrating these woody species into food crop production systems in simultaneous combinations, some of the benefits of natural long-term fallows such as recycling nutrients, suppressing weeds, and controlling erosion on sloping land, could be realized without having to keep the land out of agricultural production. The practice consists of growing arable crops between hedgerows of planted shrubs and trees, preferably leguminous species that are periodically pruned to prevent shading to crops (Fig. 1). The biomass obtained by pruning the trees and shrubs during the crop-growing season is put back to the alleys as a source of mulch and green manure. Besides, leguminous woody species add nitrogen to the system through biological nitrogen fixation (Table 2).

Many studies on alley cropping, of both biophysical and socioeconomic nature, were undertaken in various parts of the tropics during the 1980s and 1990s. Indeed, alley cropping was the most widely researched topic in tropical agroforestry during that period. In interpreting the results of these studies, some experts have used the data to defend alley cropping, others to denigrate it. But, the merits or demerits of alley cropping, or for that matter, any agroforestry technology, cannot be judged on the basis of any single criterion or short-term result. Benefits of yield and economic returns from multiple products such as fuelwood and fodder, and the possibility for avoiding the risk associated with monocultural production systems must be carefully weighed against drawbacks.

Relatively limited ecological adaptability and comparatively higher labor demand are the two key issues concerning alley cropping. The provision of nutrients through decomposing mulch, a basic feature of alley cropping, depends on the quantity of the mulch as well as on its quality and time of application. If the ecological conditions do not favor the production of sufficient quantities of mulch (as is the case in dry tropics), there is no perceptible advantage in practicing alley cropping. The issue of high labor demand is associated with the pruning of the shrubs and the incorporation of the biomass in the field. There are also some issues of pest management problems of mixed species stands as well as newly introduced species, and tree-crop competition for growth resources such as nutrients, water, and light. All these issues have contributed to poor rates of farmer adoption of alley-cropping technology.

Fig. 1 Tropical alley cropping. Fast-growing, coppicing, nitrogen-fixing shrubs and trees (“Fertilizer Trees”) are grown in rows 4–8 m apart in crop fields and pruned periodically (4–6 week intervals); the succulent and easily decomposable tree biomass so obtained is returned to the cropped alleys as a source of nutrient for crops. The photo shows *Gliricidia sepium* grown with maize (*Zea mays*), a practice followed by thousands of farmers in eastern and southern Africa. Photo credit: ICRAF, Nairobi, Kenya.

Table 2 Global distribution and area of different agroforestry system sub-groups^a.

AFS sub-group	Major AF practices	Distribution (major agro-ecol./geographical regions) ^b		Approx. area (million ha) ^b	
		Tropical	Temperate	Tropical	Temperate
Multistrata systems	Homegardens	Humid: wet, moist, and montane (rainfall >1000 mm year ¹)		100	
Tree intercropping	Shaded perennials		Forest farming		
	Alley cropping	Rainfall >800 mm year ¹	??	50	50
Silvopasture	Trees on farmlands	Throughout tropics	??	550	50
	Cut-and –carry and browsing	Wet and moist; rainfall >1000 mm year ¹		300	150
	Grazing under trees	Semi-arid to arid	N. America, Europe, subtropical highlands		
Protective systems	Windbreaks, shelterbelts	Semi-arid and arid lands; coastal areas	N. America, Europe, China	200	100
	Soil conservation hedges	Sloping lands in higher rainfall areas	N. America (Riparian buffer strips)		
	Boundary planting	Throughout	Windbreaks		
Agroforestry woodlots	Firewood and fodder	Drylands		50	
	Land reclamation	Degraded lands (eroded, salt-affected)			
TOTAL				1250	350

^aEstimates based on reported values in the literature.

^bIncludes potential areas for adoption.

Improved fallow with “fertilizer trees” is a related agroforestry technology that has been promoted in nutrient-depleted African soils. Basically, one or a few (mixed) tree species, usually biological nitrogen fixers, are planted at high density as a substitute to natural fallow, to achieve the benefits of the latter in a shorter time of 2–3 years versus 15–20 years of natural fallow. In this case also, the production of biomass in planted fallows as well as the potential of planted fallows to ameliorate soil fertility is controlled by several factors: environmental conditions, soil type, land degradation, length of the fallow period, density of tree planting, tree management, and soil and climatic conditions.

In temperate regions, alley cropping refers to growing herbaceous (agricultural) crops in the alleys between rows of widely-planted trees that are planted in single or grouped rows (Fig. 2). This arrangement allows the use of farm machinery and equipment and reduces the need for manual labor. Black walnut (*Juglans nigra*), a valuable timber- and nut-producing tree is the species most widely used in alley cropping in North America. The common spacing adopted is 12.5 m between tree rows and 3 m between trees within a row (270 trees ha⁻¹). The driving force behind most temperate-zone alley cropping are the economic benefits from the intercrop. Soil

conservation in gently sloping lands could be an additional advantage. Various aspects of this practice have received considerable research attention in the eastern and Midwestern USA and Canada. Other similar systems in the temperate regions include traditional intercropping practices used in the establishment of fruit and nut trees including olive (*Olea* spp.) and grapes (*Vitis* spp.) in Europe, with pecan (*Carya illinoensis*) trees in southeastern U. S., and with paulownia (*Paulownia* spp.) trees in China.

The most widespread form of agroforestry, in terms of the area involved, is perhaps the extensive intercropping under scattered stands of trees, particularly in the semiarid regions of sub-Saharan Africa and Asia. The so-called parkland system of sub-Saharan Africa (Fig. 3) extends across the entire semiarid belt from Senegal in the west to Ethiopia and Kenya in the east. It originated from the practice of the traditional shifting cultivation in which farmers conserved in their fields the trees that are desirable for shade, fodder, fruits, and medicines. The trees that are most common include *Faidherbia albida*, *Parkia biglobosa*, and *Vitellaria paradoxa*. The understory species include both crops such as millet (*Pennisetum glaucum*), cassava (*Manihot esculenta*), cotton (*Gossypium* sp.), maize and others depending on climatic and soil conditions, as well as grasses for animal grazing, where animals are let loose for grazing over crops residues and grasses. The practice is therefore considered as extensive intercropping or silvopasture.

Multistrata systems

Intensive, multispecies, tree-based farming systems such as homegardens, shaded perennial stands, and other complex agroforests are common agroforestry practices in the humid and subhumid parts of the tropics, especially in the lowlands (Fig. 4). The structural and functional diversity and various other characteristics of these systems have been well described and reviewed. Homegardens have a long tradition of providing food and nutritional security as well as environmental sustainability in smallholder production systems, often in heavily populated regions of lowland humid tropics in South- and Southeast Asia, and to a small extent in other tropical and subtropical regions. Although a few systems that have some similarities to tropical homegardens can be found in parts of the temperate regions as well (e.g., the satoyama system in Japan), intensive multispecies homegardens are a unique agroecosystem of the tropics.

Shaded-perennial systems that involve growing tree crops such as coffee (*Coffea* sp.) and cacao (*Theobroma cacao*) under the shade of overstorey tree species (Fig. 5) represent another traditional example of high-intensity crop combination that has some unique ecological features and commercial value. In addition to coffee and cacao, several of the tropical fruit-and-nut producing tree species that are harvested annually or at shorter intervals are often grown in association with understory- or overstorey species. In some situations, the species combinations and management features of these systems are very similar to those of homegardens such that, at the landscape- and village level, there is a continuum of plant associations from homegardens nearer homes to multistrata tree gardens away from the homes.

Characterized as the epitome of sustainability, these multispecies tree-crop combinations are excellent examples of efficient land-management systems by smallholder farmers. With heavy reliance on human (often family) labor for the farm operations, conventional tillage operations involving machinery are minimal or absent in such systems. Some of the distinguishing ecosystem sustainability features of these systems include efficient and “closed” nutrient cycling facilitated by continuous litterfall and decomposition and very little export of nutrients from the system by way of harvested products, the reliance on organic manure

Fig. 3 The Parkland system of sub-Saharan Africa. Deliberate integration of various trees and shrubs on crop- and grazing lands is a dominant traditional practice in extensive semiarid to sub-humid regions in sub-Saharan Africa. The trees provide food, fuel, fodder, medicinal products, building materials, and saleable commodities. The picture shows the shea tree (*Vitellaria paradoxa*) along with sorghum (*Sorghum bicolor*) crop. Inset: Women carrying head-loads of harvested shea fruits for processing. Photo credit: Peter Lovett.

Fig. 4 Homegardens of Jamaica. Homegardens that consist of intimate, multistory combinations of various trees and crops around homesteads provide food and cash security as well as social and esthetic benefits to millions of farm households around the tropics. The picture shows a homegarden with various fruit- and nut-producing trees such as breadfruit tree (*Artocarpus*), mango (*Mangifera indica*), and papaya (*Carica papaya*); and other food- and cash crops such as plantains (*Musa* spp.) and coffee (*Coffea* sp.) in a homegarden in Jamaica. Fig. 5 *Coffea* sp. with *Erythrina* in Costa Rica. Shaded perennial system. Shaded perennial-crop systems involve growing shade-tolerant commercial species such as coffee (*Coffea* sp.) and cacao (*Theobroma cacao*) under overstory shade trees. The photo shows coffee (dark-colored bush) under *Erythrina poeppigiana*, a leguminous tree (light-colored overstory) in Costa Rica. The tree is pollarded (pruned) two to three times a year to regulate shade received by the coffee bush.

and plant materials with consequent avoidance of chemical-fertilizer use, and predominance of deep-rooted trees, which collectively contribute to the high levels of C sequestration and climate-change mitigation in these systems, as evidenced by the recent studies in the homegardens of Kerala, India, and the shaded cacao systems of Bahia, Brazil.

Protective agroforestry systems

These systems encompass the use of trees and shrubs for exploiting their ecosystem-protection benefits by planting them as windbreaks, riparian buffers, soil conservation hedges, and similar other configurations. Windbreak practices include shelterbelts, timber belts, and hedgerows, and are planted and managed as part of a crop or livestock operation. Field windbreaks are used to protect a variety of wind-sensitive row, forage, tree, and vine crops, to control wind erosion, and to provide other benefits such as improved bee pollination of crops and wildlife habitat (Brandle et al., 2009). For livestock, windbreaks help reduce animal stress and mortality, feed and water consumption, and odor, while timber belts are managed windbreaks designed to increase the value of the forestry component. Shelterbelts are also planted along coastal areas to reduce the impact of sea encroachment and protect crops from salt-water damage. Riparian and “upland” buffers are strips of permanent vegetation, consisting of trees, shrubs, and grasses that are planted and managed together. Riparian buffers are placed between agricultural land (usually crop land or pastureland) and water bodies (rivers, streams, creeks, lakes, wetlands, etc.) to reduce runoff and non-point source pollution, stabilize stream banks, improve aquatic and terrestrial habitats, and provide harvestable products (Fig. 6). Upland buffers are placed along the contour within agricultural crop lands to reduce runoff and non-point source pollution, improve internal drainage, enhance infiltration, create wildlife habitat and connective travel corridors, and provide harvestable products. As discussed under alley cropping, the frequently pruned rows of trees and shrubs planted across the contour in crop production fields help reduce soil erosion and the pruned biomass serves as a source of nutrient to crops or can be used as animal fodder. Riparian buffers are a common feature of the landscape in the U.S. North Central region as well as in Canada. However, it is not a common land-use system in the European countries, and therefore the need to enhance riparian plantings in Europe has been discussed by Englund et al. (2021).

Silvopasture

Silvopasture that combines trees, forages, and shrubs/trees with livestock operations is another type of agroforestry practice that is popular in both tropical and temperate regions. Broadly, there are two major forms of silvopasture: grazing- and tree-fodder systems. In grazing systems, cattle are allowed to graze on pasture under widely spaced or scattered trees (Fig. 7), whereas in the tree-fodder systems, the animals are stall-fed with fodder from trees or shrubs grown in blocks (fodder banks) on farms. Most silvopastoral systems in Africa and other developing regions of the world involve extensive open grazing by free-roaming animals under scattered natural stands of trees and shrubs mostly in semiarid to arid areas, as in the parklands of sub-Saharan Africa. More intensive grazing systems of silvopasture are practiced in Latin America where animals are penned in parcels of land with barbed wire living-fence and grazing is regulated. Such organized “silvopastoral systems are also becoming popular in the extensive Cerrado

Fig. 6 Riparian buffer. region of Brazil. The most intensive silvopastoral system is the stall feeding of animals by fodder from trees grown elsewhere, which is a very common practice in smallholder farming systems of Africa and South America. The grazing system of silvopasture has recently gained prominence as an environmentally desirable approach to managing degraded pasture lands in industrialized countries. Silvopasture embodies the goals of desirable management practices for climate-change mitigation (especially in terms of grazing and manure addition) and C sequestration. Additional benefits of silvopasture include water quality improvement, soil conservation, esthetics, and providing shade to cattle (animal welfare). Alternative land uses including sustainable forest management, outdoor recreation, and ecotourism, and most encouragingly silvopasture, are considered highly compatible with traditional ranching and includes several elements of best management practices for ranchers.

Tree woodlots and specialty crops

These terms are used to denote agroforestry practices that are undertaken for special situations and needs. Examples include growing tree woodlots as fodder banks (for production of cut-and-carry tree-fodder), boundary planting of trees for production of firewood, small timber, poles and fence posts; tree planting for reclamation of degraded lands such as saline soils and mined land; establishing tree woodlots for biomass and bioenergy production such as in the Canadian prairies, growing specialty products such as ornamentals, honey, and high value crops (e.g., ginseng, shiitake mushrooms) for niche markets; and a whole host of such “non-conventional” land-use systems. The extent of people and areas involved and the economic benefits derived from such activities are seldom documented. Among these activities only large-scale tree woodlots would count as major activities in terms of carbon sequestration and climate change mitigation, although all would be important for their economic, social, and cultural benefits.

One of the best ways of reclaiming areas degraded by severe soil erosion, acidity, salinity or alkalinity, and other forms of land degradation is by planting tree species that are adapted to such conditions and leaving the land under the tree woodlot for several years to 20 or more, depending upon local conditions, before planting crops or fodder grasses is considered. Several such programs, under the banner “wasteland development,” supported by various government agencies and with the involvement of nongovernmental organizations and local communities are popular in India. Another example of large-scale implementation of protective agroforestry is the “fallow regeneration” that is gaining momentum in different parts of arid and semiarid sub-Saharan Africa. For example, the recent rejuvenation of the centuries-old parkland agroforestry systems of the Sahel, through the spread of farmer-managed natural regeneration has been documented to have occurred on nearly 5 million hectares in Niger alone.

Agroforestry and ecosystem services

The concept of agroforestry is based on the expected role of on-farm and off-farm tree production in supporting sustainable land-use and natural-resource management. While the aboveground and belowground diversity provides more stability and resilience for the system at the site level, the system provides connectivity with forests and other landscape features at the landscape and watershed levels. These ecological foundations manifest themselves in providing environmental quality and ecosystem-service functions, those commonly associated with AFS being soil improvement, water quality enhancement, biodiversity conservation, and C sequestration/climate change mitigation and adaptation.

Soil improvement

One of the tree-mediated benefits of considerable advantage in the tropics is that trees and other vegetation improve the productivity of the soil beneath them. Research results during the past three decades show that three main tree-mediated processes determine the extent and rate of soil improvement in agroforestry systems. These are: (i) increased nitrogen input by N_2 -fixing trees, (ii) enhanced availability of nutrients resulting from production and decomposition of tree biomass, and (iii) greater uptake and utilization of nutrients from deeper layers of soils by trees, the roots of which extend much deeper into the soil than roots of common crops; however, the research base on role of trees in the uptake of nutrients from different soil layers in agroforestry systems is comparatively limited.

Nitrogen-fixing trees (NFTs) and other “fertilizer trees” are a valuable resource in agroforestry systems. Farmlands in many parts of the developing world generally suffer from the continuous depletion of nutrients as farmers harvest without adequately fertilizing or fallowing the land. One promising way for overcoming the acute problem of the low nutrient status of soils, such as African soils in general, is to enable smallholders to use fertilizer-tree systems (Fig. 1) that increase on-farm food production. Some of the widely held assumptions about their benefits could, however, be wrong or incomplete. Because of methodological difficulties in quantifying N_2 fixation, especially in older trees, our understanding of the extent of N_2 fixation, and, therefore, the benefit that is actually realized by using NFTs in agroforestry systems is unsatisfactory. Furthermore, it is not clearly understood how much of the N_2 that is fixed by a NFT is actually utilized or potentially made available to an associated crop during its growth cycle, and how much goes into the soil’s N store for eventual use by subsequent crops.

Biomass decomposition patterns vary greatly among agroforestry tree species. Several biomass (litter)-quality parameters, based on the chemical composition of plant tissues, have been developed to interpret these patterns: ratios of C to N, polyphenols to N, lignin to N, and (polyphenols/lignin) to N. Using this information, we can develop management strategies to manipulate the decomposition of plant biomass in agroforestry systems, thereby regulating the rates of nutrient release in the short term, and improving soil fertility, via improved soil organic matter status, in the long term. Compared to our knowledge of aboveground biomass additions in agroforestry systems, much less is known about the dynamics of belowground biomass.

The other major avenue of soil improvement in agroforestry is through soil conservation. When properly designed and managed, agroforestry techniques can contribute to ecosystem protection and restoration functions by reducing water- and wind erosion and enhancing soil productivity.

The presence of deep-rooted trees in the system can contribute to improved soil physical conditions and higher soil microbiological activities under agroforestry. About 2 billion ha of land, a third of total farmland, in developing nations are estimated to be degraded through erosion, salinity, and fertility depletion. The potential of agroforestry to reduce the hazards of erosion and desertification as well as to rehabilitate such degraded land and to conserve soil and water has been well recognized. The soil ameliorative potential of agroforestry systems has recently been demonstrated in the temperate zone as well.

Water quality enhancement and nutrient interception

The so-called “safety-net” effect of tree roots – the ability of deep-rooted trees to absorb nutrients that have leached below the rooting zone of agronomic crops and recycling them via leaf litter and fine root turnover and thus improving the nutrient-use efficiency in the system as a whole – could have an important application in the heavily fertilized sandy soils that have low nutrient retention capacities. The capacity of tree roots to capture nutrients from the deeper soil horizons can enhance nutrient storage in the plant-soil system and thereby reduce the amount of nutrients that might otherwise be transported to ground and surface water through runoff and leaching. Research during the past decade has shown that riparian forest buffers can remove significant amounts of sediment, nutrients, and pesticides from both surface and subsurface waters and thus reduce non-point-source pollution of water bodies in the industrialized regions.

However, if riparian buffers are not established on all agricultural streams within a watershed, the nutrient levels in the stream can remain high and encourage eutrophic conditions. For example, in a study in Washington Creek Ontario, Canada (Plascencia-Escalante, 2008), upstream nutrient loading resulted in high nitrate and phosphorus levels in water adjacent to riparian plantings. However, the shade created by the riparian trees reduced the solar radiation incidence on the water and thereby prevented periphyton growth or algae bloom. The study suggested that algae blooms can be prevented even under high nutrient levels in the water if adequate shade is provided by the riparian trees. In the same study, algae blooms were observed in the same stream where there was no shade or riparian tree planting. Fig. 8 depicts the gap fractions associated with two riparian buffer types; natural forest and rehabilitated riparian buffer.

Biodiversity conservation

When landscapes are increasingly being fragmented and remaining patches of natural vegetation are reduced to isolated habitat islands consequent to human activities, mixed species AFS could play a significant role in helping to maintain a higher level of biodiversity and provide greater landscape connectivity. This can occur in at least three ways: (i) intensification of AFS leading to reduced exploitation of protected areas, (ii) increasing biodiversity in working landscapes through the expansion of AFS into traditional farmlands, and (iii) increasing the species diversity of trees in farming systems. Where croplands occupy most of the landscape, riparian forest buffers and field shelterbelts can be essential for maintaining plant and animal biodiversity, especially under a changing climate scenario. The trade-offs between ecosystem conservation and agricultural production can convincingly be addressed by shifting the view from the plot to the landscape scale and integrating biodiversity-friendly land-use systems such as agroforestry into development strategies.

Carbon sequestration and climate change mitigation

Agroforestry systems are often perceived to have higher potential to sequester carbon (C) than comparable single-species crop or pasture systems. The underlying premise is the niche complementarity hypothesis, which states that a larger array of species in a system leads to a broader spectrum of resource utilization, making the system more resilient, and implies that plant species in a mixed system use resources in a complementary way. The estimates of global annual C storage in AFS range from 0.29 to 15.21 Mg ha⁻¹ year⁻¹ above-ground, resulting in pools of 30–300 Mg C ha⁻¹ up to 1 m depth in the soil (Table 3). Recent studies under various AFS in diverse ecological conditions have shown that tree-based agricultural systems, compared to treeless systems, stored more C in deeper soil layers near the tree than away from the tree, and higher soil organic C content was associated with higher species richness and tree density. Furthermore, C3 plants (trees) have been found to contribute to more stored C in the silt clay fractions (<53 mm diameter) that constitute more stable C than C4 plants, in deeper soil profiles.

Fig. 8 Hemispherical photos taken under the water surface under two Natural Forest (NF) and two Rehabilitated Area (RA) sites at Washington Creek. Both land sites had over-stream riparian vegetation. (A) NF 1 Total gap fraction: 19.73% and Canopy cover: 81.7% (B) NF 2 Total gap fraction: 14.30% and Canopy cover: 86.7% (C) RA 1 Total gap fraction: 12.21% and Canopy cover: 87.79% (D) RA 2 Total gap fraction: 12.49% and Canopy cover: 89.51%. The amount of C sequestered in AFS depends to a great extent on environmental conditions and system management. Based on these outcomes, the potential role that AFS can contribute to climate-change mitigation and adaptation strategies is now being recognized and pursued in many development programs around the world.

The expectations of AFS in terms of environmental benefits are different between tropical and temperate regions. In the tropics where small family farms, subsistence food crops, and declining soil productivity are common features, the emphasis on the role of trees in numerous and diverse AFS is on improving the soil quality of agricultural lands and providing food and nutritional security. On the other hand, environmental protection is the cornerstone of agroforestry motivations and applications in temperate (industrialized) regions; it needs to be noted however, that although there is a tendency to equate “temperate” with “industrialized” regions, some temperate countries (or temperate regions of countries) such as China, Russia, Chile, and Argentina may be less motivated by environmental concerns than countries such as Canada, the US, Europe, New Zealand and Australia. In the tropics, soil-related issues such as soil fertility improvement, soil and water conservation, and reclamation of saline-, acid-, and other degraded soils have been major areas of agroforestry research and application during the 1980s and 1990s. Although these are environmental quality issues, they were pursued mainly as a means of augmenting the soil’s capacity to produce crops sustainably. In temperate regions, on the other hand, agroforestry was seen more as an environmental protection opportunity through the exploitation of the beneficial role of trees for water-quality enhancement in agricultural watersheds, reduced wind and water erosion, etc. In both situations, however, the focus was at the local or regional scale. During the past several decades, environmental issues of a global scale such as carbon sequestration/climate change and biodiversity conservation have become increasingly important.

System-level carbon sequestration in temperate agroforestry land-use systems (Canada)

Tree-based intercropping (alley cropping) system – A case study

The case study results presented here are from a long-term tree-based intercropping research project that was initiated in 1987 on a 30-ha site at the University of Guelph Agroforestry Research Station, Ontario, Canada (43° 32' 28" N latitude, 80° 12' 32" W longitude). Ten tree species namely, silver maple (*Acer saccharinum*), Hazelnut (*Corylus avellana*), white ash (*Fraxinus americana*), black walnut (*Juglans nigra*), Norway spruce (*Picea abies*), Hybrid poplar (*Populus* spp.), red oak (*Quercus rubra*), black locust (*Robinia pseudoacacia*), willow (*Salix discolor*), and eastern white cedar (*Thuja occidentalis*) were planted and annually intercropped with either corn (*Zea mays*), soybean (*Glycine max*), or winter wheat (*Triticum aestivum*). Tree rows were spaced at 12.5 or 15 m apart with a within-row tree spacing of 3 m or 6 m. The soil type is sandy loam (Typic Hapludalf). Crops were planted between the tree rows every year according to local ‘standard’ cultural practices.

Soil organic carbon (SOC) gains and carbon sequestration in trees were monitored from the early 1990s to 2018, a period of over 25 years. The high rate of poplar leaf biomass addition ($1 \text{ Mg C ha}^{-1} \text{ year}^{-1}$; Thevathasan and Gordon, 1997) over a total period of 8 years resulted in an absolute increase of SOC of approximately 1% close to the tree row at 15 cm soil depth, and this effect extended into the alley for up to approximately 4 m. This is about a 35% relative increase (% difference between 3.25 and the mean of 2.32 and 2.50) in SOC close to the tree rows over the given period of time and reflects leaf biomass inputs in the early 1990s, when trees were small and the major portion of litterfall was distributed close to the tree row (2–3 m) (Table 4). By 2002, the poplar trees were 14 m tall and leaf biomass was evenly distributed across the crop alley up to distances of 15 m. This resulted in a slow but inexorable increase in SOC in the middle of the crop alley, as illustrated in Fig. 9.

At the age of 25-years, the same system was investigated for carbon sequestration in soil and in trees by Wotherspoon et al. (2014). The study investigated hybrid poplar, Norway spruce, red oak, black walnut and white cedar when they were intercropped with soybean. Total C stocks for poplar, cedar, oak, walnut, spruce and a soybean sole-cropping system were 113.4, 99.4, 99.2, 91.5, 91.3, and 71.1 t C ha⁻¹, respectively at a tree density of 111 trees ha⁻¹, including mean tree C content and soil organic C stocks (Fig. 10). Net C flux for poplar, spruce, oak, walnut, cedar, and soybean sole-crop were +2.1, +1.6, +0.8, +1.8, +1.4 and – 1.2 t C ha⁻¹, y⁻¹, respectively. Results suggest that integrating these five tree species into a soybean agricultural system contributed to

Table 4 Poplar (*Populus* spp.) litterfall distribution in a poplar–barley intercropping system during the 1993 and 1994 growing seasons when trees were 6 and 7 years old respectively, Guelph, Ontario, Canada.

Distance from the poplar tree row (m)	Litterfall biomass ($\text{Mg ha}^{-1} \text{ y}^{-1}$)	
	1993	1994
0–2.5	2.67 ± 0.04	2.76 ± 0.14
2.5–6.0	0.52 ± 0.05	0.61 ± 0.06

Fig. 10 System level greenhouse gas emission reduction potential of five tree species commonly found in tree-based intercropping systems over the past 25 years in comparison with a conventional agricultural system in southern Ontario, Canada. Source: Wotherspoon A, Thevathasan NV, Gordon AM, and Voroney RP (2014) Carbon sequestration potential of five tree species in a 25-year-old temperate tree-based intercropping system in southern Ontario, Canada. *Agroforestry Systems* 88: 631–643.

greater atmospheric CO₂ sequestration potential when the intercropped tree systems were compared to a conventional agricultural system.

Even though the net flux for the soybean sole-crop was negative ($-1.2 \text{ t C ha}^{-1} \text{ y}^{-1}$), when a crop rotation such as corn-soybean-wheat is considered, agricultural SOC can be maintained, if not increased with proper Best Management Practices (BMP) (Ijzerman et al., 2022; Wotherspoon et al., 2014). However, the presence of perennial trees provides an additional pathway to increase C capture in agricultural systems, as indicated in this study.

At the same study site, it was interesting to note the change in carbon sequestration as the system matured. Ijzerman et al. (2022) reported system-level C sequestration (above and belowground tree C + SOC) for four tree species grown on the same site, although

Fig. 11 Mean total system C (t C ha^{-1}) + SE for four tree species in a 31-year-old tree-based intercropping system in southern Ontario, Canada and a monocropped soybean field ($n = 5$), to a depth of 30 cm. Total system C includes SOC stock and tree/soybean C content. a, b, c, d, e means with different superscripts between cropping systems are significantly different at $P < 0.05$. Source: Ijzerman MM, Bazrgar AB, Gordon AM, and Thevathasan NV (2022) Quantification of the carbon sequestration potential of a 31-year-old tree-based intercropping system in southern Ontario, Canada. *Advances in Environmental and Engineering Research* 3: 1–14.

the trees were 31-years old when data were collected in 2018. When comparing Fig. 9 (system age = 25 years) and Fig. 10 (system age = 31), the increase in system-level C sequestration associated with respective trees species and in the soil is obvious.

Results presented in Fig. 11 align with studies done on the same site in previous years. Peichl et al. (2006) reported that the poplar Tree-based Intercropping (TBI) system had 16.0 t C ha^{-1} more than a barley monocropped system, 13 years after establishment. Wotherspoon et al. (2014) reported that, at a tree density of $111 \text{ trees ha}^{-1}$, hybrid poplar, white cedar, red oak, black walnut sequestered, respectively, 42.3, 28.3, 28.1, 20.4 and 20.2 t C ha^{-1} more than a soybean monocrop, 25 years after establishment. Although total C was highest in the poplar TBI system, which is in agreement with previous studies (Thevathasan and Gordon, 2004; Peichl et al., 2006), an abatement in net assimilation rates was observed, possibly due to tree age. However, slow-growing species such as Norway spruce, red oak, black walnut and white cedar were found to add continuously larger amounts of carbon as they continued to mature (Ijzerman et al., 2022).

While earlier studies provide evidence that high initial C sequestration was attributed to fast-growing species such as hybrid poplar, Ijzerman et al. (2022) have highlighted the importance of incorporating slow-growing spruce and oak species for long-term C storage. This may suggest that for fast-growing tree species management strategies such as relay planting, where there is a secondary planting around 10 years after the initial TBI establishment, may provide continuously high C sequestration rates as the TBI system matures. This would allow for each species to contribute maximum system C sequestration benefits to the TBI system.

Carbon sequestration in riparian buffer systems (RBS) in southern Ontario, Canada

Ofosu et al. (2021) compared the SOC (0 to 60 cm soil depth) between different RBS that were established on previous agricultural lands and associated adjacent agricultural fields. SOC quantities within the different RBS types were significantly higher than values reported for adjacent agricultural fields (Fig. 12).

The above results show that within watershed areas in the province of Ontario, if a 15 m wide RBS was established on either side of the stream, significant gains in SOC can be realized in the top 60 cm of the soil layer. This accumulation will be in addition to the C sequestration in trees in (above and belowground biomass) the riparian buffer area. The same authors (Ofosu et al., 2022) reported SOC and biomass carbon associated with different riparian buffer types. The results are presented in Fig. 13.

The results from these studies reveal a great opportunity for climate change mitigation in the province of Ontario, Canada, in other jurisdictions in Canada, and other temperate nations. In Ontario, there are 150,000 ha of watersheds associated with 36 Conservation Authorities (<https://www.ontarioconservationareas.ca/>). The province of Ontario therefore has the potential to sequester carbon in the long-term along many water bodies if riparian buffers are prioritized in the land holdings of the Conservation Authorities.

Fig. 12 Comparison of mean soil organic Carbon stocks (Mg C ha^{-1}) in diverse riparian buffer systems (based on equivalent soil mass basis) and their adjacent conventional agricultural fields (0–60 cm depth) in Southern Ontario, Canada, 2017–2018. Means followed by same letter are not significantly different, Tukey's multiple comparisons of means ($P \geq 0.05$). [Coniferous (AB = Ausable buffer, CF = cedar forest), Deciduous (NF = natural forest, RA = rehabilitated buffer), Grass (HM1 = Hullet Marsh 1, HM2 = Hullet Marsh 2, GRL = Grassland, GRB = Grass buffer)]. Concluding remarks: The role of agroforestry in land management in the 21st century

Agroforestry began to attract the attention of the international development and scientific community in the 1970s as a means to increasing and sustaining agricultural production in marginal lands and remote areas of the tropics that did not directly benefit from the Green Revolution. Thanks to the research and development efforts at various local, regional, and global levels, agroforestry is today recognized as having the potential to offer much toward sustainable land management and environmental integrity in poor

and rich nations alike. Recent reports on the role of agroforestry in land management in the 21st century have identified food security, climate change mitigation and adaptation, and other ecosystem services as the key areas where the impact of agroforestry systems could be conspicuous in the immediate future.

In sub-Saharan Africa, which is home to three-quarters of the world's "ultra-poor" (incomes of less than US\$ 0.50 per day), approximately 218 million people, roughly 30% of the continent's total population, struggle with hunger daily. Soil-fertility depletion, exacerbated by continuous cropping without nutrient inputs in the inherently poor soils is a major challenge in the dryland ecosystems that dominate these regions. Reversing this trend and restoring soil health in the smallholder African farming systems has become a major development policy issue on the continent.

In the temperate regions of the world, agroforestry practices and principles contributing to economic and environmental services are now being more recognized by landowners. However, high establishment and labor costs associated with agroforestry land-use systems is a challenge for wider adoption in this region. Adoption of practices to strictly meet environmental, ecosystem and conservation goals must be supported by well-planned government policies that provide incentives for tree-based farming systems. These incentives can be in the form of full subsidies to integrate trees into agricultural landscapes, cost-shared programs, and reduction in property taxes for contributing to pro-environmental or ecosystem services. Mandatory environmental regulations such as the preservation of water quality in agricultural streams by establishing riparian buffers and windbreak systems to reduce soil erosion can also enhance adoption. Development of carbon credit programs (sale of C credits = enhanced economic return) is also a novel approach given the current emphasis on climate mitigation efforts promoted in this region.

Agroforestry is a key approach to the integration of climate change adaptation and mitigation objectives, often generating significant co-benefits for local ecosystems and biodiversity. Synergies between climate change adaptation and mitigation actions are particularly likely in situations involving income diversification with tree and forest products. These options also reduce the susceptibility of land use systems to extreme weather events, enhance soil fertility, and favor the conservation and restoration of forest and riparian corridors. While existing multistrata and tree intercropping systems will continue to provide substantial climate change mitigation benefits, large-scale initiatives in grazing land management, working trees in drylands, and the establishment of vegetative riparian buffer and tree woodlots are the most promising agroforestry pathways for both adaptation and mitigation. Sequestration of carbon in soils and in the biota, along with payments to resource-poor farmers for the ecosystem services rendered, would be a timely win-win strategy in the fight against food-insecurity and global warming.

The role of agroforestry in carbon sequestration is now well articulated for many agroforestry systems. Consequently, there is considerable interest in the creation of bio-carbon investment funds to channel carbon offset payments from developed countries to stimulate more carbon sequestration while simultaneously enhancing the livelihoods of small landholders and the environment. These investments will encourage development pathways resulting in higher landscape-level carbon stocks. Major public investment in the farming community can reward farmers for ecosystem services that their enterprises provide to society, in both the developed world and the emerging economies such as China and India. This suggests that the integration of trees into agricultural systems will be a major opportunity in the coming decades.

The gains and developments of more than five decades of agroforestry research and development are certainly impressive. In particular, the second half of the 1990s witnessed a large number of top-quality research endeavors and specialized publications. Undoubtedly, agroforestry is now on a firm scientific footing and is today no longer a mysterious enigma that defies science and scientific principles, as it was perceived two decades ago. Agroforestry is well on its way to becoming a specialized science at a level similar to those of crop and forest science. These hard-earned scientific gains need now to be put into practice in terms of solving the problems alluded to in this chapter. Process-oriented research needs to be extended to hitherto under-researched aspects of agroforestry, and a rethinking is also needed on overall research and development efforts at all levels (local, regional, and global).

Relatively under-researched aspects include the "agro" (i.e., crop) component of agroforestry. All crops and their cultivars/varieties that are used in agroforestry research today are those that have been developed for sole-crop conditions, and they may not be the best for situations such as those that occur in agroforestry systems. Domestication and improvement of indigenous and underexploited trees is also an area that can yield immediate dividends. Furthermore, research endeavors have so far been mostly limited to plot- and field-levels and now need to be scaled up to landscape, watershed, and ecosystem levels. Another important area of research priority is policy and market issues pertaining to the valuation of non-timber forest products. Enhancing the adoption potential of agroforestry technologies through improved extension techniques and methodologies for impact assessment are two additional areas that need immediate research attention. In general, all agroforestry land-use systems discussed in this chapter have their strengths and challenges (weaknesses). Even though these practices promote environmental, ecological, economic and social aspects, the outcomes are often influenced by 'internal and external' elements. Nair et al. (2016) have summarized these elements using SWOT analysis (Fig. 14). Agroforestry systems, be they practiced in the tropics or temperate regions, provide many basic needs and ecosystem services, and thus contribute to many regional developmental goals. These under-exploited systems have the potential to develop into a set of major land-use options in the 21st century.

Acknowledgment

This chapter is an updated version of a previous chapter in this volume by P.K. Nair (Nair, 2004), and draws heavily on that publication as well as current and previous work by all 3 authors, as cited in this chapter. Certain passages and texts have also been taken from Nair (2013) *Agroforestry: Trees in Support of Sustainable Agriculture* (<https://doi.org/10.1016/B978-0-12-409548-9>).

	POSITIVE	NEGATIVE
	Strengths	Weaknesses
INTERNAL 	Food- and nutritional security	Long-term investment
	Monetary benefits: higher farm incomes and income diversification	Relatively unimproved farming practices
	Risk reduction; Satisfaction	Difficulty in commercialization
	Multifunctionality	Lack of research and technical skills
	Niche complementarity in maximum utilization of natural resources	Lack of institutional recognition and policy support
	- Ecological diversity - Enhancement of ecosystem and environmental services	- Difficulty in extrapolating to other areas - Labor intensive in relation to managing both components (trees and the annual crops)
	Landscape aesthetics	
EXTERNAL 	Opportunities	Threats
	Potential government support	Potential future tax on "subsidiary income"
	Increase in land value	Uncertainty about future government regulations
	Environmental and recreational benefits	Excessive lopping and exploitation of preferred species
	Climate-smart agriculture and climate-change mitigation	Changes in Wood import policies
	Enhancement of socio-cultural values and land ethics	- Policy and governance issues related to input subsidies - Local land tenure regulations may inhibit adoption - Change in ownership of the land can threaten the longevity of the practice/s

Abstract

Rangeland management is essential to the sustainable use of rangeland by protecting, improving and restoring the rangeland's basic resources—soil, water, plants, and wildlife. Important management principles include livestock species, stocking rates, grazing systems, fire suppression or prescribed burning, and water supply. Management must be flexible and adaptive in response to uncertainties and variation. The effects of management actions need to be monitored on the ground and/or with new methods such as remote sensing or modeling. Many rangelands are affected by constant vegetation changes, soil degradation, and social and environmental changes (climate change). Future rangeland management must address these challenges through adaptive management strategies.

Introduction

Rangelands are the dominant land cover type on Earth. There are different definitions of rangeland, but most are a combination of land cover type, referring to vegetation or even a biome, and land use; only the emphasis between these aspects varies. There are general features that are characteristic of rangeland:

- (1) (semi-) natural vegetation
- (2) suitable for extensive grazing or browsing by wildlife and/or domestic animals
- (3) non-cultivated land

Rangelands can be defined as “lands that support predominantly native or naturalized vegetation capable of sustaining native or domestic grazing and/or browsing ungulates.” These characteristics distinguish rangelands from cropland and pastures, where the latter is used for the production of adapted, forage plants for domesticated livestock. Here, the land is seeded, usually with introduced species, sometimes with native plants and combined with intensive land use.

Rangelands have a high spatial and temporal heterogeneity, which is inherent (e.g., climatic variability, topographic features, soils, plant communities) as well as generated by disturbances (grazing, fire). They provide a suite of provisioning, regulating, supporting and cultural ecosystem services, meeting the growing demand for livestock products (Erb et al., 2016) with carbon sequestration, biodiversity conservation (Kremen and Merenlender, 2018), and recreation certainly being among the most important.

Fig. 1 Global map of rangelands as derived from World Wildlife Fund terrestrial ecoregions map. Data download: <https://www.worldwildlife.org/publications/terrestrial-ecoregions-of-the-world>.

Rangelands are diverse and not restricted to specific ecosystems. Mostly they are found in arid areas characterized by limited rainfall, often sparse vegetation and climatic extremes. However, they also occur in all bioclimatic zones of the world, with conditions ranging from arid to sub-humid, and average annual precipitation spanning 150–1500 mm (Fig. 1). Rangelands exist on all continents, with the highest percentages in sub-Saharan Africa and Asia (except the Middle East). Estimates of the proportion of the world covered by rangeland vary depending on the definition and the regions included, but rangeland is generally thought to account for about 47–51% of the Earth's terrestrial surface, or 68.5 million km² (IPCC, 2014). Higher values of 54% are also documented when deserts are included in the calculations (ILRI et al., 2021). The extent of rangeland is constantly changing as portions of it are lost by conversion to cultivated land (in continental temperate zones) or, conversely, rangeland area is increased by conversion of forested land to human-made grassland (in equatorial and subtropical zones) (ILRI et al., 2021).

Due to different climates and soils, rangelands vary in their biota, which has led to classification into rangeland types. Basic rangeland types by climate and vegetation are grassland, shrubland, woodland, savanna, and tundra (Fig. 1). Grasslands are treeless and dominated by plants of the *Gramineae* family. Savannas, forests, and shrublands are distinguished primarily by their varying tree cover, while tundra areas are characterized by a treeless plain with tufted perennial plants and lichens in arctic regions. In addition to these types, there are numerous subtypes, some of which are defined only for distinct regions and specific criteria in certain parts of the world (e.g., Eurasian steppe, South African Highveld, American prairies, and South American pampas).

Rangelands are used by a large number of people in pastoral systems or livestock-dependent societies. The number of pastoralists is currently estimated to be 200 million, worldwide (FAO, 2022). Pastoralists are commonly defined as people who derive more than 50% of their income from extensive livestock production and livestock products. However, there is a huge variety of pastoral systems around the world, categorized by economy (subsistence or commercial pastoralists), the contribution of agriculture to income (pure pastoralists and agro-pastoralists), management strategies or proportion of movement (mobile and sedentary) (for references see Sandhage-Hofmann (2016)).

Rangeland management

Livestock and grazing are still the main land uses in rangelands, even though increasing types of use are being added by, for example, tourism, agro-pastoralism, conservation, mining, and energy production. There are several, mostly linked, strategies for sustainable management for livestock, where the overall goal is to maintain rangelands in good condition, sustaining their basic ecosystem functions and services. Rangeland management developed as a discipline that aims to ensure sustained yields of rangeland products while protecting, improving and restoring the basic range resources: soil, water, plants, and animal life. The management has evolved from a pure exploitation of rangelands (end of 19th and beginning of 20th century), to steady-state management (early last century), followed by ecosystem management (late 1970s), to today's resilience-based approach of rangeland management (Briske, 2017). This means people changed from being simply users of the rangeland resources to being stewards of the resources. Ecological and social change, uncertainty, and incomplete knowledge are part of resilience-based rangeland management. Resilience can be defined as the capacity of a system to absorb disturbance and reorganize to maintain function, structure, feedbacks and identity. Exceeding the resilience, ecosystems may form alternative stable ecosystems. The resilience-based approach also recognizes different spatial scales. Rangelands are viewed as social-ecological systems resulting in stakeholder engagement. Consequently, rangeland

management must be flexible and adaptive enough not only to tailor grazing and management activities to suit unpredictable environmental conditions, but also to respond to changing policy, economics, demands for ecosystem services, and management capacity (for references see [Briske, 2017](#)). Such flexibility and adaptability constitute a serious challenge, especially given climate change and decreasing profitability of range-fed livestock. Adaptive management concepts have the ability to cope with heterogeneity and disturbance and respond to changes, and have replaced static management prescriptions in rangeland management ([Allen et al., 2017](#)).

Even though rangeland management has developed from exploitation to an approach that is sustainable for the rangeland and its users and responsive to unexpected events, the basic grazing principles—animal species, stocking rate, grazing systems (duration and season of grazing), and fire—are still the mainstays).

Animals

The management of livestock and their grazing behavior is an important topic with respect to sustainability and the worldwide problem of rangeland degradation, which is assumed to be caused also by overgrazing. When selecting livestock for a particular rangeland, the rangeland manager must decide about livestock species and the composition of classes in the herd, as well as stocking rate and stocking strategy.

Domestic livestock

Approximately 12 species of domesticated animals dominate global livestock production ([Table 1](#)). The most important of these are cattle ([Fig. 2](#)), sheep, and goats, with global populations of approximately 1.5, 1.3, and 1.1 billion (B), respectively (including indoor housing, which represents only a small portion mainly in Europe). Livestock numbers continue to grow to meet increasing demand for meat, particularly in Asia, Africa and South America. During 2000–20 the increase in cattle, sheep, and goats numbers was 33%, 11%, and 50%, respectively ([FAOSTAT, 2022](#)).

Livestock species are adapted differently to various types of rangeland, and five key factors are involved in the selection of appropriate livestock species: climate—including animal responses to climate change ([Mitchell et al., 2018](#)), water requirement, vegetation, topography, and socio-economic conditions.

- (1) Climatic conditions include air temperature, where livestock species differ in withstanding climatic extremes. It is important to recognize that not only the air temperature, but also the thermoneutral zone (TNZ) of the animals and their thermal safety are important for the selection of species ([Mitchell et al., 2018](#)). The TNZ is defined as the range of effective ambient temperatures (EAT) at which an animal does not have to regulate its body temperature actively. For healthy cattle, a range between 5 °C and 25 °C is recommended, whereas sheep and goats can cope with higher and lower temperatures. The TNZ is influenced by many factors, including breed, age, body condition, type of coat and pigmentation of the hide and hair, wind speed, and humidity ([Table 1](#)).
- (2) Adequate water supply is critical for livestock health and production. Water requirements vary significantly depending on the livestock species, and consumption of water is influenced by numerous factors like age, gender, pregnancy, lactation, activity, type of diet, and feed intake ([Table 1](#), [Fig. 3](#)). In addition, environmental properties control water intake. For example, water requirement of beef cattle rises as temperatures rise from 4.4 °C to 32.2 °C ([Fig. 3](#)).
- (3) Depending on food preference, herbivores are divided into three major groups: (i) Grazers such as cattle, horses, and mules eat primarily grass and have the digestive capabilities to process large quantities of relatively low-quality forage. They have a limited

- ability to choose between plants and plant parts. (ii) Intermediate feeders, which include sheep, can graze selectively and eat certain plant parts such as small leaves or buds. Sheep tend to eat more green forage than grass. (iii) Browsers such as goats are able to chew twigs and strip individual leaves from woody stems, resulting in a higher quality diet than cattle. In extreme situations such as forage shortages, most livestock adapt to different plant species.
- The topography of the rangeland can be a decisive factor in the selection of animals. Goats and sheep are versatile animals and can live in diverse environments (Table 1). This includes grazing and or browsing in varied, steep, and rocky terrain. In contrast, cattle are not well adapted to rocky and steep grounds and prefer flat areas.
 - Socio-economic conditions can influence the selection of livestock species. This is especially true in traditional rangeland systems, where certain species and their numbers are associated with wealth and power.

Wildlife

Many rangelands are also subject to grazing or browsing by wildlife (Holechek et al., 2010). In the past decades, game ranching has become an increasingly important option to benefit from rangeland. This includes bison production, which is becoming increasingly popular in the United States and Canada. In sub-Saharan Africa, numerous wildlife ranches have been established since the 1960s because they provide increased or supplemental income to livestock production (Bothma et al., 2004). The growing demand to see wild animals in nature is being met by a growing supply of (guided tours) over farm areas. Another reason for the increase of game ranching, apart from economic considerations, is the fact that native animals are better adapted to local conditions (foraging, water, climate), particularly in areas with extreme climate conditions (Holechek et al., 2010). Climate change is likely to intensify this trend.

Multiple species grazing

A promising tool for balancing the impacts on rangeland caused by one livestock species is applying multi-species grazing systems, i.e., keeping two or more animal species on the same rangeland simultaneously (Martin et al., 2020). Benefits of diversity in multi-species grazing systems include resource use efficiency, biodiversity conservation, productivity, profitability, and animal health and welfare. For example, different feeding habits among livestock species can reduce competition for feed if the dietary overlap between the species is low and forage availability is sufficient.

Stocking rate

The use of appropriate stocking rates is one of the most critical decisions for successful range management. The stocking rate is defined as the number of livestock per unit land area for a given period and is the basic relationship between livestock and forage resource (SRM, 2015). Stocking rate affects livestock production, rangeland condition and economic outcome. The objective is to balance the forage demand of grazing animals with that of forage production over an annual forage production cycle. The amount of forage an animal requires depends on its size, age, species, and whether it is growing, pregnant, lactating, or dry. There are several schemes to relate these various conditions to an “animal unit” (AU); most of them use a calculation based on the weight of the animal. Others use animals of different sizes, which are directly proportional to their weight. Table 2 gives an overview of the most common calculations for the animal unit.

Based on the animal unit or livestock unit, an expected amount of forage is used to calculate the stocking rate. The Society for Range Management calculates that one animal unit would consume 2–2.6% of its live weight per day, which represents 9.1 kg of dry

Table 2 Common livestock units/animal units of different regions worldwide.

Region	Europe	North America	South America	Tropics	Australia	New Zealand	Asia
Unit equivalent	Dairy cow	Beef cow	Cattle mature	Tropical cow	2-year-old Merino sheep	Ewe with one lamb	Cattle mature
Weight equivalent	600 kg	455 kg	455 kg	250 kg	45 kg	55 kg	455 kg
Livestock equivalents							
Cattle mature	1.00	1.00	0.70	0.70	8.0	6.3	0.65
Cattle (<2 years)	0.40	0.80			7.0	4.5	
Horse	0.70	0.80	0.65	0.80	10.0		0.65
Sheep	0.17	0.15	0.10	0.10	1.1	1.0	0.1

matter (DM) per day⁻¹ or 3318 kg DM year⁻¹ (Holechek et al., 2010). Although fewer studies are available for the tropics and subtropics, estimates are comparable and approximately 2.5% of live weight would be consumed for one tropical livestock unit (TLU), which represents 6.25 kg DM day⁻¹ and 2281 kg DM year⁻¹.

The following equation can be used to calculate the stocking rate:

$$\frac{(\text{Total land area (acre)}) \times (\text{end of season standing forage (lbs. acre}^{-1}) \times (\text{forage utilization (lbs. acre}^{-1}))}{(\text{AU forage demand per AU per day (lbs. acre}^{-1}) \times (\text{number of days grazed}) *}$$

*Bidwell et al. (2017).

The high variability of forage production and the variability in annual and interannual precipitation are the main challenges for setting appropriate stocking rates. There is a common understanding that stocking rates should be flexible and adaptable, and include the consideration of social parameters such as current perceptions, prevalent norms, and historical contexts, especially in communal land (Rasch et al., 2016). The use of flexible stocking rates, which are adapted to fluctuating annual forage production or stocking rates, that are adjusted based on precipitation during the current growing season (adaptive management) are preferable to fixed stocking rates, which are based on the carrying capacity of the land. Carrying capacity (CC) is the maximum number of animals that a rangeland can support over the long term without degrading the natural resources of the area. It can be seen as a basic guideline for animal numbers in the management unit, because on many rangelands the carrying capacity is less than forage production.

Stocking rates also depend on the amount of forage available on the rangeland, measured at the end of the season (Redfearn and Bidwell, 2017). Forage production is highly variable and not only affected by climate, but also by soil fertility, texture, and vegetation management. Traditional methods for measuring the end of season standing biomass rely on time-consuming hand clipping in long-term exclosures at the end of season. This is increasingly being replaced by remote sensing imagery from satellites or, more recently, drone estimates that can support adaptive rangeland management during the grazing season by providing real-time estimates of forage production (Fig. 4) (Liu et al., 2019). Additional factors affecting stocking rates include the grazing system practiced, distance to water, slope, fire, and climatic variation (see Sandhage-Hofmann, 2016).

Calculation of appropriate stocking rates must include wildlife densities, because livestock and wildlife may compete for the same forage. For nature reserves or game farms, which have become increasingly prevalent, especially in Southern Africa, knowledge of "wildlife units" is necessary. The different feeding behaviors of wildlife (browsing, grazing, intermediate) and the widely varying diets of wildlife species make it necessary to consider both grazing and browsing units (GU, BU) for calculating wildlife stocking rates (Table 3), taking into account the grazing and browsing capacity of rangelands. This allows for a more accurate determination of the overall stocking rate.

Grazing system

The introduction of grazing systems as a management option was implemented quite recently in the use of rangelands; in the 20th century. Previously, rangeland had been characterized by free-ranging herds of wild herbivores, and the traditional transhumant movement of cattle farmers (Briske, 2017). Animals moved in response to forage supply, fire, predators, and other factors (Teague et al., 2011). Early in the 20th century, settled farmers put continuous grazing pressure on localized areas. In view of rangeland degradation, various kinds of grazing systems have emerged to stop deterioration and to handle the spatio-temporally heterogeneous distribution of biomass, which is a common feature of most rangelands.

Continuous and rotational grazing are the two dominant grazing systems in the world. Continuous grazing is the most common grazing system in rangelands (Teague et al., 2011); it allows livestock to graze throughout the year (year-round continuous grazing) or during a specific period of the year (continuous grazing during the growing season). In this continuous grazed system, no resting periods for vegetation and soil are introduced. Livestock graze forage selectively and tend to use preferred local areas. Consequently, the stocking rate in these frequently grazed patches may be much higher than the intended stocking rate. Therefore, spatial patterns may develop in which some areas and plants are heavily grazed while others are not or only lightly used. In addition, livestock are concentrated around water points where permanently high grazing pressure can lead to the development of grazing gradients and consequently soil and vegetation degradation (Sandhage-Hofmann et al., 2015).

In rotational grazing systems, the rangeland is divided by fencing into several paddocks or camps among which the animals are moved regularly, with a resting period for recovery of soil and vegetation between each grazing interval. Multiple specializations of rotational grazing systems exist, which differ mainly in the length of grazing or resting time (Table 4). Longer grazing periods of several weeks and months are contrasted to short grazing periods between 2 and 10 days. In this context, the term Holistic Planned Grazing™ describes an intensive, rotational, time-controlled approach.

Rotational grazing or multi-paddock grazing systems are often applied rigidly rather than adaptively, and advantages compared to continuous grazing are low. But recently, adaptive multi-paddock grazing includes short grazing periods, moderate grazing

Table 4 Basic rotational grazing systems with a single herd.

<i>Grazing system</i>	<i>Stocking rate</i>	<i>Length of grazing</i>	<i>Length of rest</i>	<i>management</i>	<i>strategy</i>
Deferred rotation	Moderate	Long	Moderate	Fixed	HPG ^a
Rest rotation	High	Short	Long	Fixed	HPG
High intensity-short duration	High	Short	12 month ^a		
			Long		HUG ^b
			> 2 month ^a		
Time-controlled grazing	High	Short			
Short duration	High	Short	Moderate		HPG
		5 days	4–6 weeks ^a		

^aHigh-performance grazing strategy for selective grazing of preferred plants.

^bHigh-utilization grazing for grazing on preferred and unpreferred plants.

during the growing season, leaving adequate plant cover followed by adequate planned recovery, and matching livestock to forage biomass.

The debate over which is the best grazing system continues. Several publications have pointed out that, despite many prejudices, research could not support the argument that the anticipated disadvantages of continuous grazing systems lead to an overall degradation of rangeland. A recent review of grazing systems around the world showed that assessments often take into account only single indicators (e.g., only soil) but not the entire rangeland system, meaning vegetation, soil, livestock, and social interactions. In addition, a positive or negative effect of a particular grazing system sometimes applies only to a particular type of rangeland, while the effect may be different in other climates (di Virgilio et al., 2019). In addition, temporal and spatial scales of the studies vary. In view of this, the benefits of rotational systems for forage production, ubiquitous use of crops, restoration of vitality and improvement of soil properties, which have been demonstrated in numerous studies, should be generalized with caution (e.g., Hughes et al., 2011; Teague et al., 2011; Kotzé et al., 2014; Sandhage-Hofmann, 2015; Roche et al., 2015, for references see Sandhage-Hofmann (2016)).

At the very least, there seems to be a consensus that adaptive, goal-oriented management systems are required, which account for spatial heterogeneity, inherent uncertainty, risk, and incomplete knowledge (Briske et al., 2020). Management is then often “learning by doing,” and managers act despite risk and uncertainty of how measures will play out. Risk and uncertainty become greater when medium- or long-term decisions are being taken.

A basic knowledge of plants and animals is essential, together with an understanding of abiotic factors like soil and climatic circumstances of the rangeland. Grazing systems and stocking rates should be variables that are used adaptively as tools in rangeland management systems. Social circumstances should also be included in considerations of the management systems. This includes the fundamental role of livestock’s safety net function in communal areas, but also prevalent norms such as the role of livestock as a status symbol (Rasch et al., 2016).

Water

The number and location of water points are important factors in controlling the movement and concentration of livestock, as well as in controlling the distribution of grazing in rangelands (Holechek et al., 2010). Water can be supplied by wells and boreholes (artesian or pumped), dams and ponds and by pumping and piping from water bodies, or sometimes by trucks (Syria and Jordan). Water pumping techniques include wind turbines, gravity distribution, solar energy, and solar panels to prevent freezing. In traditional systems, particularly in semi-arid areas, wells, water harvesting, and storage techniques such as *birka* (cisterns) in Somalia and *hafir* (dug tanks) in several Arabic countries are common. Sometimes, water is transported by truck to the rangelands (Syria and Jordan).

Ideal distances between water points depend on the livestock species and age, topography, climate, season, type of vegetation and grazing system. Livestock are averse to walking long distances to water. In general, goats and herded sheep can be without water for a longer time than cattle as they will probably derive water from food. They were reported to depend on a 3–5-day watering, while cattle rely on water supply within a period of 3 days. Of cattle’s activity, 80–90% takes place within a range of 5 km from water, meaning that 5–6 km between water points could be optimal in terms of achieving a moderate grazing distribution and also preventing overgrazing. However, several studies in various countries have suggested different recommendations, from 1.6–3.2 km (North America), 6–10 km in dry seasons for cattle and 4–5 km for sheep (South Africa), 3 km for sheep, 6 km for cattle, and 7 km for red kangaroos (Australia) with variations according to wet or dry seasons (for all references see Sandhage-Hofmann (2016)).

A balanced supply of water is recommended, because a widespread availability of water, allowing herbivorous mammals to continue grazing, can lead to feed shortages when there is a lack of rainfall (Holechek et al., 2010). In contrast, there may be negative effects on various ecological properties; especially in large paddocks with few water points, the areas near water tend to be overgrazed.

Fire

Fire is critical to maintaining biodiversity and ecological processes in rangelands and is a natural component of most of them. However, the beneficial effect of fire has been underestimated for a long time and prescribed burning has been reduced, resulting in a recent increase in number and extent of wildfires (Starns et al., 2019). But planned burning and/or fire suppression are both essential parts of rangeland management. Prescribed burning is the use of fire under specific conditions to increase forage productivity, reduce litter, improve growth of favorable plants, combat undesirable plants (e.g., brush encroachment), and control pests and diseases. Fire can also have a positive effect on soil by increasing pH, plant nutrients and exchangeable cations, and NO_3^- immediately after burning. Negative effects may also result, such as water repellent surfaces which hinder water infiltration and enhance runoff and erosion. It is important to adapt the fire regime, intensity, frequency and season, to local conditions to avoid negative effects on plant performance and soil. In addition, improper use can be a threat to human life, property, community assets, air quality, and other rangeland aspects. Prescribed burning differs from the reaction-driven treatment that is generally applied following wildfires (Holechek et al., 2010).

Monitoring

The effectiveness of management actions can only be assessed through monitoring. Monitoring strategies include seasonal observations with short-term adjustments of management as well as long-term monitoring with, consequently, long-term management strategies to cope with interactions between livestock pressure, droughts, invasive species, bush encroachment, wildfires and climate change (McCord and Pilliod, 2022). In relation to the evolution of adaptive rangeland management, adaptive monitoring is required which responds to new management questions, changing environmental and socioeconomic conditions, improved monitoring methods, models, tools, and experience in implementing the monitoring program. Monitoring requires (i) setting objectives and questions, (ii) selecting methods and sampling locations, (iii) collecting data, and (iv) analyzing and interpreting the data. Evaluation of these results should then be used to adjust management, if necessary. Monitoring tools developed from field-based quantitative and qualitative measurements may evolve to new techniques with remote sensing tools plus machine learning and model development. Promising tools for monitoring rangelands are drones and increasingly smart-phone cameras (sometimes even with an integrated LiDAR sensor). Historical and present trends of land cover data can also be used to evaluate previous management actions, and to guide future management decisions.

Rangeland degradation

Rangeland degradation is defined as a reduction in the ability to provide ecosystem functions and services such as forage production and quality for livestock, water quality and quantity, biodiversity conservation, or carbon sequestration. Rangelands are highly dynamic ecosystems that include changes in ecological and social properties at different temporal and spatial scales. However, interactions of social and ecological factors can cause transitions to undesirable alternative states where ecosystem services are negatively affected. In arid and semiarid ecosystems, these transitions are often observed not as gradual, predictable succession, but as abrupt regime shifts to alternative states ("state changes") (Archer et al., 2022). Currently, many rangelands are altered, as evidenced by persistent changes in vegetation (plant species composition), soil degradation, or invasive species (Nandintsetseg et al., 2007; Stafford Smith et al., 2007; Williams and Jackson, 2007; Dai, 2011, for references see Sandhage-Hofmann (2016)). Drivers of ecological and social changes in rangelands can be summarized into (i) human population growth and the associated unsustainable use of natural resources; (ii) climate-induced warming and increasing climate variability (iii) accelerated land conversion and fragmentation, including exurban development and (iv) reduced effectiveness of traditional common governance, where developing countries are facing additional challenges like aging, a shift in societal preferences away from rangelands and low profit margins in livestock production (Briske et al., 2020).

Rangeland degradation is a major problem worldwide, but the assessment of degradation varies significantly due to differences in the methods, benchmarks, and scales (temporal and spatial) under consideration, which lead to different estimates about the extent (Lund, 2007; Reed et al., 2015). Some authors have suggested that more than 50% of the world's rangeland area is degraded, while others estimate that it is up to 75% (Seymour et al., 2010; for references see Sandhage-Hofmann (2016)). The rangeland atlas estimated degradation based on the productivity status of rangelands, which resulted in an area of 20% (excluding deserts), where developing countries are more affected (ILRI et al., 2021). Rangeland degradation is usually first perceived in the condition of the vegetation, but other ecological properties are also affected by degradation phenomena.

Vegetation

Degradation of rangeland vegetation has been attributed to a combination of overstocking with livestock, deforestation, woody-plant encroachment, and invasion by non-native plant species. Historical-cultural and social conditions also contribute, as does global climate change. Livestock overgrazing is considered to be one of the main causes of vegetation degradation by decreasing both the productivity and resilience of host species, reducing vegetation cover, increasing unpalatable species, and decreasing species diversity.

Grazing (and browsing) is a natural ecological process in all rangelands. Herbivores consume plant material including its compounds, such as proteins and carbohydrates, which are digested and provide them with energy and nutrients (Teague et al., 2011). Dung and urine release close the loop. Grazing has many direct or indirect effects on the vegetation. Whether they improve or degrade the vegetation depends on the timing, duration, kind of grazing, rangeland type, but also aridity. For example, plant species richness improves in wet regions when grazing is compared to non-grazing, while plant richness is negatively affected in dry regions, and stocking rates explain variation in the data (Gao and Carmel, 2020). In general, studies have reported that light and moderate stocking rates have no or positive effects on plant productivity and composition, especially in fertile rangelands. Causes are attributed to increasing spatial heterogeneity or vegetation patchiness of plant communities caused by selective grazing patterns of the herbivores. In contrast, high long-term stocking rates lead to overgrazing and negative effects on the forage value of rangelands due to depletion of some preferred species and their replacement by non-preferred species. Overgrazing is defined here as repeated continuous grazing which exceeds the recovery capacity of the plant community and creates degraded rangeland (SRM, 2015). Effects on vegetation can be manifold, e.g., the herbaceous biomass changed from perennial grasses to annual species, the portion of bare soil increased; species changed from palatable to unpalatable species, or, shifts in grass species dominance

occurred with (over-) grazing (for references see [Sandhage-Hofmann \(2016\)](#)). In this category, invasive species and encroachment of woody plants deserve special attention.

Invasive species

Invasion of plants in rangelands is a major threat worldwide. In general, the term invasive plants refers to the intentional or unintentional introduction and spread of exotic plant species (alien) into an area where they did not previously exist. These plants have the ability to thrive and spread aggressively outside their native range, eventually resulting in the replacement of indigenous plant species. Invasion processes include introduction, establishment, spread and impact, where invaders' survival and abundant establishment is ensured by early reproduction, large numbers of seeds and the ability to become established easily in degraded environments. Disturbances such as human agro-pastoral activities or alterations in patterns of fire regimes could be the causes of invasion. Or, management-induced changes in native plant communities might provide opportunities for invasion or a further increase of alien and native species ([Poland et al., 2021](#)).

The challenges posed by invasive plants in rangelands are of serious concern and are expected to increase in the next several decades. Invasive terrestrial plants can change key system processes such as productivity and nutrient cycling. Depending on their plant functional traits, invaders can accelerate carbon cycling and can lead to carbon storage decline in rangelands. They impact plant community structure and diversity, alter forage production for livestock and wildlife, and threaten livestock production. Depending on their life cycle they can increase soil erosion and deplete nutrients and reduce soil moisture ([Poland et al., 2021](#)). Despite negative effects, sometimes invasive plants can help to restore degraded rangelands and provide some benefits to the system. Invasive species can lead to the development of so-called "novel ecosystems." In future, the control of these novel ecosystems should not be based on the restoration of the original ecosystem alone, but should also consider the potentially higher biodiversity and ecosystem services these new ecosystems may have.

Woody plant encroachment

Most rangelands consist of a mixture of herbaceous and woody vegetation. In the last century, this balance has been disturbed and shifted in favor of shrubs and trees at the expense of the herbaceous (grassy) layer in many areas of the world. This so-called woody plant encroachment (WPE) is expressed in a global vegetation greening by native or non-native woody plants ([Fig. 5](#)). The distinction from "invasive species" (see above) is not always clear because alien woody plants (e.g., *Prosopis* in Kenya) also contribute to the phenomenon of WPE. Worldwide, 10–20% of drylands have already undergone encroachment by woody plants, but the real rates of encroachment vary depending on the region and methods of assessment. It is estimated that absolute encroachment rates range from zero to 3.3% cover year⁻¹, with an average of 0.85% cover year⁻¹. Rates are higher in the early stages of bush encroachment, and decrease with time. The WPE occurs in a wide range of climates, with one of the most striking shifts toward woody plants occurring in the Arctic, known as the "greening" of the Arctic ([Myers-Smith et al., 2020](#)).

Drivers and causes of WPE are inter-related and context specific. These factors include alterations in fire and grazing regimes, exclusion of browsing megaherbivores, landscape fragmentation, and land abandonment as internal factors as well as elevated atmospheric CO₂, rising N deposition and climate change as external drivers ([Archer et al., 2022](#)). Environmental variables such as soil, topography, and precipitation regimes modulate the intensity and extent of WPE. The effect of grazing, in particular, has long been criticized. Extended periods of heavy grazing suppress the production of herbaceous forage, creating space for the proliferation of woody plants. The lower grass fuel loads reduce the frequency and severity of wildfire, which seems to control the spread of bushes. Biological feedbacks like soil-fauna activities, or enhanced nutrient cycling beneath the bushes, may promote WPE. Nowadays, it is well accepted that causes of WPE are an interaction of several variables where the main factor can vary in different regions. Effects of WPE are manifold, including effects on carbon pools in biomass and soils ([Sandhage-Hofmann et al., 2020](#)), hydrology, biodiversity, nutrient cycling, composition of plants, invertebrates and vertebrates, and increased risks of vector-borne diseases.

Fig. 5 Bush encroachment, North Western Province, South Africa. Photo: Sandhage-Hofmann.

Several strategies have developed to combat WPE. “Brush management” tries to eliminate woody plants by cutting, burning, and chemical clearing to foster the recovery of herbaceous biomass, but results are variable, probably also because of the depletion of soil seed banks. Adapted stocking rates are also necessary to avoid overgrazing with its above-mentioned effects. Livestock systems with multiple species, grazers and browsers, can not only stabilize livelihoods through diversification and grazing, but browsing of megaherbivores could counteract WPE. As WPE is not necessarily associated with functional decline, it can have positive effects on ecosystem services (e.g., carbon sequestration) and management should carefully balance livestock production with other benefits of WPE.

Soil

Soil degradation is widespread in rangelands and characterized by the decline and reduction of ecosystem goods, and services provided by soils. It includes physical, chemical, and biological processes.

Physical degradation

Compaction

Trampling by animals is the main cause of alterations in physical properties of the soil. The force that a grazing animal imposes on the soil is a function of the weight of the animal and the area of contact between the animal’s hooves and the soil surface. The pressure varies between different animal species, with cattle applying the highest pressure (Table 5). One single livestock or animal unit (LSU, AU) can produce pressure on the soil beneath a single hoof of about 123 kPa, which may significantly increase when the animal moves (Bilotta et al., 2007).

The direct negative effect of trampling on soils is compaction, which affects bulk density, water infiltration rates, aggregate stability, penetration resistance and porosity (Roesch et al., 2019). Compaction itself is dependent on soil properties like texture or water content, with for example sandy soils are less prone to it. Volume and connectivity of large pores are the main properties related to infiltration and transport of water and air in soils, and both decrease with soil compaction. Macropores are particularly sensitive to deformation, and their compaction leads to higher bulk density and increases the risk of water runoff. Higher soil bulk density because of increased animal trampling has been observed for different grazing animals and rangeland systems. In a meta-analysis of grazing impacts on soils, Byrnes et al. (2018) confirmed findings from other authors, that all livestock strategies and intensities increased soil compaction, where the effect was greatest under heavy grazing, and if comparing rotational and continuous grazing, continuously grazed soils were more compacted. Trampling by animals may also lead to aggregate disruption, which is most common in arid and semiarid rangelands. Aggregation is an integrative indicator for the soil’s overall quality and closely related to several ecosystem services, and functions, including physical and hydrological functioning of soil, and sequestration of organic carbon. Trampling by animals results in a loss of stable aggregates, which decreases infiltration rates (for references see e.g., Roesch et al., 2019). Aggregate stability decreases with increasing grazing intensity and in places where animals congregate such as water-points, shaded areas, and fences (Teague et al., 2011). Soil compaction by trampling of animals depends on soil texture, moisture, and type (Sandhage-Hofmann et al., 2015), grazing intensity and strategy (Fig. 6).

Soil loss

The loss of soil from land surfaces by erosion is widespread globally and adversely affects the productivity of natural ecosystems like rangelands. In arid and semiarid rangelands, soil erosion has been widely recognized as an important soil degradation process and is considered one of the main factors responsible for declining soil fertility and desertification (Okin et al., 2001; Michaelides et al., 2009; Bestelmeyer et al., 2006; for references see Sandhage-Hofmann (2016)). Fine-size soil particles are lost, as is organic matter, which plays an essential role in the formation of stable aggregates. Plant nutrients are lost with water and or wind erosion.

Livestock grazing with high stocking rates and inflexible stocking strategies are thought to increase the susceptibility of rangelands to wind erosion by reducing vegetation cover and modifying the stability of the soil surface, but responses to management are complex and can differ between rangeland types, soil types, vegetation, and livestock species. For example, taller vegetation can inhibit erosion by reducing wind speed, for example (Gao et al., 2014). Soil erosion is influenced by vegetation cover, plant community composition, distance between grasses, and size of and connectivity between bare soil patches. Furthermore, the

Table 5 Live weight, foot area and static pressure of different livestock species.

	Mass kg	Total foot area cm ²	Static pressure kPa
Cattle	306–612	264–460	98–192
Sheep	40–54	55–84	48–83
Goats	40	55	60–73
Horses	400–700	736	54–95
Camels	450–650	1644	27–40

Fig. 6 Degradation at a water point, North Western Province, South Africa. Photo: Sandhage-Hofmann.

occurrence of physical or biological soil crusts affects rates of erosion, where grazing destroys soil crusts directly through trampling, and indirectly by altering vascular plant communities that interact with the crust communities. Quantifying the impact of rangeland management on rates of wind and water erosion remains a challenging task and therefore many soil erosion models and applications have been developed. But, the discrepancy between modeled systems and reality is great, and often model calibrations are only valid for a specific region (Batista et al., 2019). Therefore, generalizations should be made with care.

Chemical degradation

Nutrients

Livestock grazing affects the contents and dynamics of nutrients and soil organic matter (SOM) through the soil–vegetation–animal system in many ways, including trampling, consumption, excreta deposition, redistribution, and export (Sandhage-Hofmann, 2016). Two contrasting pathways influence nutrient concentrations in rangeland soils: (i) enrichment and (ii) loss. Enrichment of nutrients occurs at locations of highest grazing pressure, where herbaceous biomass consumed by livestock is returned to the soil in form of dung and urine, as well as through a centripetal nutrient flow to the water holes at natural water points. While urine contains high concentrations of urea-nitrogen, potassium, sodium and chloride, dung contains relatively high concentrations of phosphorus, calcium, magnesium and organic nitrogen. The patches of excreta cover only a small proportion of the grazed area, and are especially large around water points, beneath trees, at kraals, or along fences (Sandhage-Hofmann et al., 2015) resulting in a spatially heterogeneous distribution of high nutrient concentrations. High stocking rates are associated with such nutrient accumulation, whereas under rotational grazing, rangeland resources are used more evenly, and manure and urine are more randomly distributed.

Nutrient losses may be caused by high grazing pressure and is accompanied by depletion of plant cover and litter input. In addition, defoliation can affect plant rates of photosynthesis, root/shoot ratios, C allocation, fine root mass, and plant root exudates (for references see Byrnes et al., 2018). Reported effects of grazing or different grazing strategies on plant nutrients range from negative to no effects (for references see Sandhage-Hofmann, 2016).

Nowadays, woody plant encroachment in many rangelands does counteract nutrient losses and improve the soils. Various processes contribute to these so-called “islands of fertility.” These include litter from leaf fall, stem flow, and through-fall; droppings from birds and mammals; accumulation of nutrients from areas beyond the crowns by means of lateral tree roots; and increased termite activity. Greater organic matter and nutrient input in encroached rangelands restores rangeland soils (e.g., Sandhage-Hofmann et al., 2020), but at the cost of palatable grass species, which threaten the livelihood of many people.

Biological degradation

Soil biological degradation involves the decline in activity and species diversity of soil biota, especially of microorganisms, which play critical roles in the cycling of nutrients, and leads to the decline of soil organic carbon, the loss of soil biodiversity and biological activity (Soto et al., 2021).

Soil organic carbon

Worldwide, a huge number of studies have evaluated the effect of grazing on soil organic carbon stocks, contents, or pools. Soil organic carbon is positively associated with many soil functions that are critical in rangeland production, including nutrient and pH buffering, water retention, and soil structural stability. It is difficult to generalize the impact that grazing has on soil carbon dynamics because the balance between soil carbon inputs and outputs in grazed rangelands varies greatly among systems. Research

has shown mixed results of grazing effects on soil organic carbon (SOC) and soil organic nitrogen (SON). In general, higher grazing intensities and overgrazing are thought to decrease soil C and N contents by directly removing above-ground herbaceous biomass, and by reducing below-ground C inputs through lower root production and higher root turnover. Continuous grazing compared with no grazing showed that continuous grazing had negative effects on C content at low, medium, and high grazing intensities. In contrast, carbon values appeared to be higher when rotational grazing was compared with no grazing (Byrnes et al., 2018). The direction and magnitude of change is influenced by many factors like climate (aridity), soil type, vegetation type, grazing management, and history of grazing. High long-term grazing intensities are leading to more bare soil patches susceptible to wind erosion and subsequent soil organic carbon loss (see above). In addition, if plant composition changes, the chemistry of plant litter, patterns of plant biomass allocation, litter production, and the spatial distribution of nutrients change. Depending on the intensity, grazing pressure may slow rates of decomposition by lowering the carbon-to-nitrogen (C:N) ratio of litter; alternatively, decreased standing biomass may accelerate the decomposition by increasing soil temperature, but decreasing soil water content may neutralize this effect. Furthermore, grazing may convert different carbon pools from a relatively recalcitrant pool into more mineralizable carbon fractions.

A recent meta-analysis (287 studies) summarized the effects of different grazing intensities on a variety of soil properties (Lai and Kumar, 2020). Results showed that of the 15 variables at 0–10 cm soil depth under heavy grazing, nine were negatively affected. This number reduced to six under medium grazing intensity. The soil properties significantly affected were bulk density, penetration resistance, soil organic carbon, and microbial community under both grazing intensities. The authors concluded that heavy grazing is more detrimental for soil quality than moderate and light grazing. But the mechanisms of the interactions between grazing and environmental factors on soil properties are still unclear and require more research.

Outlook

Rangelands and pastoral societies face social and environmental challenges, such as changes in land tenure, land-use, intensification, fragmentation, settlement, population growth, wildlife conflicts, conservation policies, and, most importantly, climate change. These changes are no longer occurring gradually, with time to adapt, but more often abruptly and unpredictably. This so-called tipping point behavior occurs when a system or parts of it cross a threshold that leads to a regime change to another, often undesirable state. Not every such regime shift is necessarily detrimental, and potentially positive changes in rangelands in the future also have to be recognized that could lead to new adapted management strategies. Degradation of rangelands continues to be a major problem, and restoration efforts are required. These include various management principles discussed above, but they must also be feasible and reasonable. The issue of benchmarking, i.e., what condition a rangeland should be restored to, should be given more consideration in the future. In addition, the culture and history of societies are important considerations. For example, planned measures may be much more difficult to implement in communal areas of developing countries with higher financial costs than in industrialized societies with commercial farmers who have the appropriate economic background. This means, culture and history of societies can be important for successful rangeland management for maintaining, improving or restoring rangeland condition.

Abstract

In this chapter we address how grassland management affects soils, recognizing that this relationship is not unidirectional, and it is driven by interacting factors such as soil texture, climate, botanical composition, production systems (grazing or mowing for hay and silage) and management practices. Grasslands that are managed for pasture, hay and silage would not naturally be grasslands, but have been established on areas that historically would have been forest but have been cleared and developed for agricultural purposes. Consequently, grasslands have diverse soil textures that influence other physico-chemical properties and processes in soil.

Key points

- The focus of this chapter is on soils under temperate agricultural grasslands, specifically those that are managed for pasture, hay and silage production.
- Soil processes in grasslands are mainly driven by soil texture, climate, botanical composition, production systems (grazing or mowing for hay and silage) and management practices (e.g., grazing intensity, fertilizer application, irrigation, re-seeding).
- Impacts of grazing on soils are affected by the degree of defoliation, urine and dung deposition and trampling, all of them influenced by stocking rates and the type of grazing system. Impacts of mowing on soils are affected by cutting frequency and soil compaction from vehicle traffic.

Introduction

What are grasslands?

Grassland is one of the largest of five major categories of ecosystem defined by the Pilot Analysis of Global Ecosystems (White et al., 2000), the others being forest ecosystems, agroecosystems, coastal ecosystems and freshwater systems. Broadly, the term grassland refers to “terrestrial ecosystems dominated by herbaceous and shrub vegetation and maintained by fire, grazing, drought or freezing temperatures.” However, the definition of grassland varies considerably across studies and authors, and their distinction from rangelands (a term often used for grasslands) can be confusing (see Rangelands chapter in this Encyclopedia). In general, we could

Fig. 1 Pasture global distribution in 2000. The Global Pastures data set represents the proportion of land areas used as pasture land (land used to support grazing animals) in the year 2000. Source: Center for International Earth Science Information Network (CIESIN), Columbia University. Global Agricultural Lands: Pastures, 2000: Global [Map]. 2012. say that rangeland supports predominantly native or naturalized vegetation capable of sustaining native or domestic grazing or browsing ungulates, whereas pastures (i.e., agricultural grasslands) are used for livestock production (Fig. 1).

The large extent of grasslands, which cover approximately 70% of the World's agricultural area, means that they are globally important for maintaining high levels of biodiversity and food production, regulating nutrient cycling and water quantity and quality, and supporting cultural services, such as recreation, tourism and cultural heritage. Globally, grasslands contain ca. 20% of global soil carbon stores and therefore play a major role in climate change (Stockman et al., 2013). However, around 49% of the area covered by grassland currently experiences some level of degradation due to overgrazing, eutrophication, land use changes, invasive species, climate extremes and fire (Bardgett et al., 2021). Agricultural grassland can be considered under three categories based on the intensity of their management:

- (1) Unimproved grassland—typically used for hay or extensive grazing and not receiving fertilizers
- (2) Semi-improved grassland—typically subject to additions of fertilizer to improve productivity and used for more intensive grazing or hay production
- (3) Improved grassland—typically plowed and re-seeded with grass species in monoculture, and heavily fertilized for intensive grazing or silage production.

Climatically, grasslands can be divided into tropical and temperate grasslands. Tropical grasslands are characterized by existing on highly weathered soils, which are more susceptible to nutrient and organic matter losses, and the dominance of C_4 grasses. In general, the typical rainfall patterns strongly affect biomass productivity and decomposition processes in tropical soils. The main threat in temperate grasslands is intensification, arising due to grazing, mowing, reseeding and inorganic and organic amendment applications, whereas tropical grasslands are threatened by overgrazing, fire and climate change. Different soil conditions and plant inputs to the soils reflect the differences in physico-chemical and biological processes in soils, such as the soil organic carbon turn-over rate (the time it takes for a carbon atom to pass from its entrance in an ecosystem to its exit), which generally is longer in tropical soils.

The focus of this chapter is on soils under temperate grasslands, which occupy 8% of the world's land area (White et al., 2000), specifically those that are managed for pasture, hay and silage production.

Grassland soils

In grasslands, soil processes are mainly driven by soil type, climate, botanical composition of the sward and management practices (Byrnes et al., 2018; Russell and Bisinger, 2015), including land use history and duration of management. Natural grasslands typically occur on Chernozems (Mollisols in US Soil Taxonomy), characterized by a thick, dark organic and nutrient rich surface horizon, but managed grasslands can occur on a wide range of soil types. Many of the grasslands that are managed for pasture, hay and silage would not naturally be grasslands, but have been established on areas that historically would have been forest but have been cleared and developed for agricultural purposes. Consequently, grasslands have diverse soil textures that influence other

physico-chemical properties and processes in soil. For example, fine-textured soils tend to have a greater water holding capacity than coarser-textured soils; in addition, fine textured particles also play a key role in soil aggregation. Precipitation and temperature directly affect primary production in grasslands as well as decomposition rates in soils. Unfavorable local weather conditions (too dry or too wet) can promote and aggravate soil physical damage, soil erosion, water quality degradation and greenhouse gas emissions—all negative effects that are associated with grazed pastures under high intensity (Soussana and Lemaire, 2014). Other climate effects are mediated via plant communities or soil faunal activity, both of which vary with climate (Ingram and Fernandes, 2001). An increase in plant biodiversity (richness and abundance) impacts positively on productivity and microbial activity (Lange et al., 2015), and can be promoted through grazing management, leading to a higher functionality of grassland ecosystems.

Soil condition can be determined through the measurement of key soil indicators, and these are crucial to develop appropriate and sustainable management strategies (Bardgett et al., 2021; White et al., 2000). For example, indicators such as soil nutrient and carbon content, soil depth, litter characteristics (mass, distribution and incorporation), soil respiration and enzymatic activity are linked to soil fertility and climate change mitigation, while soil stability and water regulation can be assessed by measuring soil organic matter (SOM), soil loss, soil aggregate stability, soil texture, bulk density, water holding capacity and electrical conductivity. Measurements of other chemical soil properties (pH, cation exchange capacity, salinity) are useful to evaluate the capacity of a soil to filter and retain pollutants.

Most grasslands have a large inherent SOM content, especially near the soil surface, that supplies plant nutrients, helps to reduce soil erosion and increases cation exchange and water holding capacities. Although the effect on water holding capacity is relatively small, organic matter creates macropores that can significantly increase water infiltration and gas transport. Therefore, in grassland systems it is vital to maintain the concentrations of SOM (Conant et al., 2017). Major organic matter inputs to grassland soils are provided by animal manures and roots (fine roots and root exudates), and relatively small amounts from plant litter as the majority of biomass is removed. All of these modify soil structure and soil biochemistry.

Soil carbon sequestration in grasslands

Temperate grasslands have an estimated soil organic carbon (SOC) sink capacity between 105 and 295 Gt C (0–1 m) according to Stockman et al. (2013). The potential of soil carbon sequestration is determined by several defining factors related to soil type and physical properties such as mineralogy, texture, stoniness, bulk density and aeration (Ingram and Fernandes, 2001). In general, under the same carbon input and climate, soils with fine texture can store more carbon than soils with coarse texture due to greater soil aggregation and the carbon protection role performed by clay and fine silt.

Increasing grassland biomass productivity, for example, by increasing nutrient application, and therefore carbon inputs to the soil, will enhance the capacity of grasslands to store carbon. However, the ability to maintain and stabilize soil carbon depends on climate, the degree of protection within soil aggregates, the soil carbon saturation level (highly dependent on soil texture), its quality and turnover rates, all factors that are strongly influenced by the types of grassland production system and management practices (Gilmullina et al., 2020; Necpalova et al., 2014).

In this chapter we address the question of how grassland management affects soil quality, recognizing that this relationship is not unidirectional, and it is driven by the abovementioned interacting factors. We also raise the question of suitability of soils for a particular type of grassland use, for example, is the land suitable for regular trafficking by heavy farm vehicles required for mowing and fertilizer spreading, or is better suited to light grazing? Can this be better managed taking account of seasonal changes (rain, snow, drought)?

Grassland production systems

Over the past 30 years, grasslands have been used increasingly for bioenergy production and there are attempts to include grass protein as part of the human diet. Nevertheless, the main purpose for producing grass within the food chain is to feed livestock that typically provide dairy or meat products for human consumption. In this sense, the main grassland production systems, classified according to the fate of the grass, are pasture, hay and silage.

Pasture is defined as land used for the production of grass together with associated species, such as legumes and forbs, which are directly consumed by grazing livestock (Fig. 2).

In many regions grazing is only possible during warmer, drier months of the year because the cessation of grass growth over winter means there is insufficient forage to feed the livestock. For this reason, the vegetation is cut to produce hay and silage that can be stored and fed to the animals. More specifically, hay is produced by cutting grasslands and allowing the vegetation to dry in the field before being pressed into bales (Fig. 3).

Silage can be produced from similar grasslands, but instead of drying before storage, it is either packed in silage clamps or in wrapped bales (Fig. 4), both of which must be airtight to enable fermentation and acidification, which preserves the forage. This results in a more easily digestible fodder that is more nutritious than hay (e.g., with higher protein content).

On many livestock farms, fields will be managed for both pasture and hay or silage (mowed grassland) in a single season, depending on the capacity for storage. However, on farms with permanently housed animal units, fields will typically be used solely for either silage or hay production with no grazing taking place.

Fig. 2 Cattle grazing on improved pasture in southwest UK. Courtesy Rothamsted Research.

Fig. 3 Haymaking on an unimproved pasture in southwest UK. Courtesy Rothamsted Research.

The management of grasslands, for either pasture or hay and silage production, impact soils in two distinctive ways: (i) the need for cutting and harvesting of grass, typically using heavy machinery in hay or silage production, and (ii) the lack of natural returns of organic matter (by excretion) to grasslands used for hay and silage production due to the lack of animals. These distinct production systems (grazed grasslands, mowed grasslands and the combination of both) and their impacts on soils form the focus of the next section.

Impact of grassland production systems on soil properties

Grassland production systems can vary in terms of their physical impact on the soil, biomass productivity, plant community structure and biogeochemical cycling, especially carbon and nitrogen cycles. Even though both grazed and mowed grasslands imply removing biomass from the system, specific factors associated with each production system can cause different impacts on soils.

Fig. 4 Collecting and wrapping silage from improved pasture in southwest UK. Courtesy Rothamsted Research.

Effect of grazing on soil properties

Impacts of grazing on soils are affected by the degree of defoliation, urine and dung deposition and trampling. There are many different ways in which pastures can be grazed, and the manner in which grazing is managed can have significant impacts on soils. Perhaps the most common management system is continuous grazing, whereby livestock are left permanently on the pasture throughout the grazing season, although stocking numbers may be adjusted according to the availability of grass. There is growing popularity for the practice of rotational grazing, sometimes referred to as “mob” grazing or adaptive multi-paddock (AMP) grazing. In these systems livestock are contained in small paddocks within larger fields. The length of time grazing is allowed within each paddock, and how long the rest period is, can vary considerably depending on the specific rotational stocking approach that is used, which can (or should) ultimately be determined by soil properties. The grazing time allowed within each paddock can vary anywhere from about 1 week to a few hours, and equally the rest period can range anywhere from 21 days up to 50+ days.

Impacts of grazing under continuous-stocking management vs. no grazing (exclosure) on soils

Continuous stocking describes a method of grazing management where animals have unrestricted and uninterrupted access to large units of land or pasture for a prolonged period of time when grazing is allowed (Allen et al., 2011). The main management variable in a continuous-stocking grazing system is the stocking density, which can be broadly categorized into light-, moderate- and heavy-stocking or grazing. There is a wide range of soil responses to different grazing intensities, and the effects are frequently inconsistent due to an array of site-specific factors which play important moderating roles (Byrnes et al., 2018). Russell and Bisinger (2015) reported that SOM concentrations are higher in grazed pastures compared with non-grazed pastures, which in turn increases soil carbon and nutrient sequestration and water-holding capacity. The positive impact of grazing on SOC has also been reported by others, even when productivity is reduced. In such cases organic matter inputs as urine and dung deposited by grazing livestock counterbalance the reduced plant inputs, and belowground inputs can be boosted as a result of a greater sward diversity (Bai and Cotrufo, 2022).

Conversely, Wang et al. (2011) reported that overgrazing resulted in decreases in soil carbon stocks in China, but this effect was reversed by exclusion of animals over 30 years. Similarly, Byrnes et al. (2018) concluded from their meta-analysis that continuous grazing, regardless of grazing intensity, significantly reduced SOC, carbon: nitrogen ratio and total nitrogen content compared to no grazing (exclosure); but reduced grazing intensity tended to lower soil bulk density and increase SOC. A recent meta-analysis by Lai and Kumar (2020) found that heavy-grazing significantly increased the soil bulk density and penetration resistance, and reduced SOC and water content, along with nitrate, microbial biomass carbon and total nitrogen concentrations compared with soils exposed to no-grazing. Moderate-grazing had a less negative impact on soils, but still resulted in significantly increased bulk density, penetration resistance, pH, and phosphorus concentration (0–10 cm) but decreased phosphorus (10–30 cm), SOC (10–30 cm) and total nitrogen (10–30 cm) concentrations. Light-grazing had minimal negative impact on soils, resulting in increased SOC (0–10 cm) and soil ammonium concentrations compared to no grazing (Lai and Kumar, 2020). Banerjee et al. (2000) reported light, continuous-grazing systems to have the largest soil microbial biomass and nutrient mineralizing activity compared to heavy, continuous or rotational grazing. Furthermore, Zhao et al. (2017) found that high-intensity, continuous grazing

results in losses of both soil bacterial and fungal communities, and an increase in the ratio of soil fungal to bacterial communities, with associated decreases in nutrient turnover rates.

The species of grazing animals can also influence the impacts of grazing on the soil. Although changes in SOC can be linked to stocking density of livestock, for sheep the stocking density generally has little impact on soil carbon stocks. [Lai and Kumar \(2020\)](#) stated that cattle grazing had a greater impact on SOC, total nitrogen and available potassium compared with sheep grazing, but less impact on soil penetration resistance.

Impacts of rotational or time-controlled grazing vs. continuous grazing on soil properties

Rotational grazing is becoming an increasingly popular form of grazing management, which involves recurring periods of grazing and rest among three or more paddocks within an area of grazing land ([Allen et al., 2011](#)). In the United States, a study by [Conant et al. \(2003\)](#) found total soil carbon was 22% higher under a rotational system compared with a continuously grazed system while [Oates and Jackson \(2014\)](#) reported that soils under management-intensive, rotational grazing had a favorable carbon content compared with soils under continuous grazing or used for making hay. In contrast, no differences in soil carbon stocks were found when comparing soils under rotational grazing with those under continuous grazing in a Canadian study.

Another grazing strategy is silvopasture, which is the practice of integrating trees, forage, and the grazing of domesticated animals in a mutually beneficial way. It utilizes the principles of managed grazing, is one of several distinct forms of agroforestry and has been identified as one of the most beneficial climate change solutions ([Feliciano et al., 2018](#)).

Effect of silage and hay production and mixed management (grazing and mowing) on soil properties

Mowing frequency, timing and cutting height impact soil properties via their influence on plant inputs to soils. In general, soil temperature, soil compaction and bulk density tend to increase as number of cutting events increase, whereas soil moisture and soil porosity decrease as a result of above-ground biomass removal. Macro and micronutrient availability can vary depending on the frequency of cutting, plant uptake and the antagonistic relationships between many elements in soils that affect their availability to plants.

One of the main impacts on soils under mowing is compaction resulting from vehicle traffic. The degree of compaction can vary, depending on machinery pressure and mowing frequency but also on soil texture (with sandy soils less prone to severe compaction than clay soils), soil structure and soil moisture. [Hargreaves et al. \(2019\)](#) reported that soil bulk density was greater in soils exposed to trafficking by vehicles rather than trampling by cattle. Therefore, silage fields, which are exposed to multiple passes by vehicles during fertilizer application, cutting, windrowing and harvesting, up to four times a year, are more prone to compaction, with susceptibility to compaction greatest when soils are wet. This has knock-on effects, reducing yield and also nutrient use efficiency due to the smaller uptake of applied nutrients. Inefficient use of nutrients can result in losses via runoff and subsequent eutrophication of surface waters, or in the case of nitrogen, increases in rates of denitrification and greenhouse gas emissions from soils. The implementation of double cropping for silage production (e.g., conventional tillage winter rye harvested in May or June followed by no-till corn silage) can improve soil structure, and increase saturated hydraulic conductivity and the resilience of the soil to traffic.

In managed grasslands in Southwest France, [Gilmullina et al. \(2020\)](#) found that mowed systems had smaller SOC and total nitrogen concentrations than grazed systems, although both systems had relatively large carbon stocks. These authors suggested that grazing was preferable to mowing because it leads to better substrate quality and more efficient microbial functioning under the same soil and climatic conditions. However, contrasting results have been observed under different climate conditions. Under an aridity gradient, [Liu et al. \(2022\)](#) reported that high-intensity grazing decreased plant species richness and SOC whereas hay production had less detrimental effects on ecosystem functions and enhanced plant species richness. In semiarid grasslands with sandy soils, alternating mowing and grazing promotes the coexistence of diverse plant species, balancing the nutrient cycling and ensuring good levels of biomass production ([Koncz et al., 2020](#)). Regarding plant diversity, there is no clear evidence that increasing plant species richness influences SOC and TN stocks under hay cut management in England. However, the presence of legumes in grasslands plays a key role in C and N sequestration ([Sollenberger et al., 2019](#)).

Vegetation recovery time after mowing is crucial to avoid soil degradation. In areas with a high frequency of hay or silage production, fertilizer application is required to compensate the depletion of soil nutrients over time ([Mayel et al., 2021](#)). However, the effects on soils of long-term applications of inorganic fertilizers and practices such as liming need to be monitored to prevent soil acidification and a decrease in soil nutrient availability.

There is some evidence that the combined management of grazing and cutting in a single season can have positive effects on soil properties ([Gavrichkova et al., 2008](#)) resulting from enhanced rhizodeposition and associated increased microbial activity. These were reported to be accompanied by decreased rates of SOM mineralization, meaning the microbial community that developed became more energy efficient. In these mixed management grasslands, soil compaction by animal trampling and vehicles is also affected by the combined effects of soil texture and climate, which can affect not only changes in soil structure but also grassland yield and N₂O fluxes. For example, damage to soil structure and reductions in silage production (as dry matter yield) have been observed in UK soils with a large clay content compared to sandier soils, mainly during cold wet weather ([Hargreaves et al., 2019](#)). In humid temperate grazed grasslands, increases in soil temperature, soil moisture and cutting events contributed to N₂O pulses

from soils in spring and summer, highlighting the fact that changes to the timing of grazing and mowing can reduce greenhouse (GHG) emissions.

In grasslands that are grazed over winter, supplementary feeding sites can result in localized increases in soil compaction from increased treading but can also have positive effects on SOM and soil nutrient concentrations, such as soil P and K (Sollenberger et al., 2019). In this case, the regular moving of feeding sites is recommended to favor homogeneity of excreta and nutrient distribution.

Management strategies for pasture, hay and silage

Grassland management strategies, such as the application of inorganic and organic fertilizers, liming and irrigation can increase carbon storage in mineral soils due to greater nutrient availability, biomass production and an improvement in soil aggregation (Conant et al., 2017), although these practices can also alter nutrient cycling and result in leaching and groundwater pollution from nutrients (Soussana and Lemaire, 2014). Many studies show the importance of optimized, sustainable grassland management that considers the local context. Conant et al. (2017) carried out a meta-analysis of 192 studies and found that fertilizer addition, increased species diversity (including legumes), irrigation, and reduced cultivation resulted in increases in soil carbon stocks of between 0.1 and 1.0 t C ha⁻¹ yr⁻¹. However, effects were specific to soil type, climate and sward mix. Grazing effects on soil and carbon sequestration also depend on grazing intensity as described above. Moderate and light grazing can improve SOC and bulk density, whereas heavy grazing can impact soil structure, reducing soil porosity and infiltration as a consequence of compaction (Mayel et al., 2021). In contrast, poorly managed grasslands can deplete SOM and alter the botanical composition, decreasing productivity and plant diversity, hence, reducing resilience of grasslands to climate change (Russell and Bisinger, 2015).

Application of inorganic fertilizers

All three grassland production systems require nutrient inputs to maintain productivity because each experiences a net removal of nutrients from the soil. Based on intensity and quantity of fertilizers applied, the order typically declines from silage to pasture and to hay (Table 1). However, due to the many interacting factors involved, it does not necessarily follow that the degree of negative impact on soils follows the same order. The objective of fertilizer application is to maintain productivity, and therefore theoretically the nutrient status of soils under each should, on average, be the same. The reason there are fewer inputs to hay soils is that typically only one cut per year will be made, whereas for silage, three cuts per year are typically made, and grazed pasture has continuous removal throughout the grazing season. However, pasture has the benefit of receiving excreted returns from livestock, thus replenishing the nutrient status of the soils, meaning they require fewer manufactured fertilizer inputs, even though the distribution of the “natural” fertilizer can be highly heterogeneous. Currently the inclusion of legumes such as clover into swards is increasing, meaning that the need to apply inorganic N fertilizers is greatly reduced due to its N fixation role, and in some cases eliminated. However, other inorganic fertilizers such as phosphate and muriate of potash are still required to provide macronutrient to the soil (P and K).

Overall, the effects on carbon stocks of nutrient applications to grassland soils are unclear because there aren't many field measurements of the effects of nutrient availability on production and carbon stocks. Schipper et al. (2017) concluded that the application of phosphorus to four flat and hill country sites in New Zealand over 24–60 years resulted in no changes in carbon stocks.

Application of organic amendments on grassland soils

Organic fertilizer refers to those organic amendments applied to soils, other than direct deposition of excreta by grazing animals, and includes animal manure, sewage sludge and compost, along with rendering waste, guano, brewery waste, digestate and other bio-wastes. They can contribute large amounts of nutrients to soils, for example, estimates of the potential amount of cattle manure produced in different countries show a range between 8,304,000.00 (UK) and 77,094,000.00 Mg y⁻¹ (US) (Thangarajan et al., 2013). They are favored from the farmer's point of view due to their potential to increase soil fertility and productivity but can be vulnerable to nutrient losses to water and the atmosphere due to priming effects and their susceptibility to promote nitrification and denitrification. Moreover, there is a concern about the potential risk of toxic elements inputs (e.g., heavy metals) mainly under

Table 1 Cutting regimes and typical fertilizer application rates for different grassland management systems.

Management	Cutting regime per annum	Typical N fertilizer rate per annum, N ha ⁻¹	Typical P fertilizer rate per annum, P ₂ O ₅ ha ⁻¹
Silage	3+ cuts	335 kg split over three applications	75 kg split over three applications
Pasture	Continuously grazed	240 kg split over three applications	45 kg split over three applications
Hay	1 cut	100 kg, single application	40 kg, single application

From <https://www.yara.co.uk/crop-nutrition/grassland/> Consulted on September 2022.

intense rainfall events when organic amendments are applied. A rigorous regulation should consider the field conditions to ensure a safe application and provide guidance. For instance, grazing is not allowed for 3 weeks after spreading sewage sludge in the UK, and there is a soil testing requirement. The method of application of organic amendments influences the form of nitrogen lost, for example, trailing shoe, splash plate.

Application of lime on grassland soils

Many grasslands are in areas of high rainfall, meaning that one of the main causes of grassland soil acidification is the leaching of cations down the soil profile. It can also be enhanced by the addition of ammoniacal fertilizer, predominantly in pasture and silage systems, and less so in hay systems. This can have important consequences for grass productivity, with the optimal soil pH typically being around 6.5 for most grassland species. To raise the pH of soils, lime is commonly applied. This can have significant impacts on soils, including increasing the availability of nutrients, especially phosphorus, as well as impacts on microbial communities. [Lochon et al. \(2018\)](#) reported that an increase in pH associated with liming resulted in both changes in microbial communities and increased microbial activity leading to increased SOM decomposition. Similar results have been seen in the Park Grass Long Term Experiment in the UK, where measurements have been taken over more than 100 years and have shown that adding lime increases SOM decomposition rates. However, effects on total SOM depend on how far the impacts on decomposition are offset by increased incorporation of carbon inputs into stabilized carbon pools.

In a study by [Sochorová et al. \(2016\)](#) hay yield was significantly increased by application of lime. Initially, the carbon content in the top 10 cm of soil also increased with liming, but decreased if inorganic nitrogen and phosphorus fertilizers were added simultaneously. Therefore, long-term hay production can lead to a reduction in soil carbon stocks. To protect soil quality, interactions between management strategies must be considered when making decisions aimed at increasing yield.

Irrigation of grassland soils

Not all grassland soils are irrigated, but climate change means that in many regions application of water is having to be considered for the maintenance of productivity, especially for silage and pasture systems. These high-production, irrigated systems differ from their dryland counterparts in nutrient requirements and losses, especially for carbon, nitrogen and phosphorus. For example, [Carmona et al. \(2020\)](#) reported that irrigated swards decreased the proportion of carbon apportioned to roots by 35% when irrigated, and in combination with an increase in root-derived carbon and changes in the forms of carbon upon decomposition, resulted in a net reduction in soil carbon. [Schipper et al. \(2013\)](#) also found that under the same phosphorus fertilizer regime, irrigated and sheep-grazed pasture treatments had up to 4.2% less soil carbon than a dryland treatment.

Under irrigation, an increase in pasture production requires more inputs of nitrogen and phosphorus to soils. If grazed, excess nitrogen from protein in the pasture is excreted in urine which can deliver nitrogen into soils at rates too high for the sward to utilize (e.g., dairy cattle urine patches contain 600–1000 kg nitrogen ha⁻¹), resulting in the surplus being available for loss as nitrate by leaching and runoff following nitrification. Because irrigation can produce large yields of pasture (e.g., 18 t of dry matter ha⁻¹ yr⁻¹), stocking rates of 4–5 cows per hectare are achievable, and if located on shallow stony soils can result in large leaching losses of nitrate-nitrogen (>60 kg nitrogen ha⁻¹ yr⁻¹) ([Chapman et al., 2021](#)).

For phosphorus losses from grassland systems, stocking rate is less important than available soil phosphorus concentrations. This is because pasture production protects the soil surface from treading damage and the loss of particulate phosphorus in runoff. Hence in contrast to dryland grasslands, much phosphorus loss from soils in irrigated grasslands occurs due to leaching in dissolved form rather than as the result of soil erosion. The magnitude of loss, however, depends on the quotient of available soil phosphorus concentrations and soil phosphorus sorption capacity. In most agriculturally productive soils, moderate or high sorption capacity can minimize losses if the soil is maintained at an agronomically optimum level (e.g., 20–30 mg phosphorus kg⁻¹ measured by Olson test, which was originally developed for neutral and alkaline soils, but is often applied across soils of all pH values), but can be insufficient if the soil is shallow or is supplied with too much or inappropriate forms of phosphorus. Indeed, over a period of 14 years, phosphorus losses in leachate increased by an order of magnitude (from 0.14 to 1.4 kg phosphorus ha⁻¹ yr⁻¹) where phosphorus was applied in effluents from housed dairy cows compared with the same amount of phosphorus being applied as superphosphate fertilizer ([McDowell et al., 2019](#)). Increased losses were caused by organic matter blocking phosphorus sorption sites and the presence of more mobile phosphorus forms in the effluent.

The type and timing of irrigation can affect nitrogen and phosphorus losses. Large losses of phosphorus have been noted (e.g., up to 42% of that applied) if irrigation was applied within 3 weeks of the fertilizer ([Hart et al., 2004](#)). Although some of these losses can be abated by using less water-soluble forms of phosphorus and reductions in phosphorus losses have been facilitated by moves toward spray irrigation.

Re-seeding

The re-seeding of pasture and silage systems is a common practice as new cultivars are developed, or mixed swards are replaced due to decreasing diversity, especially loss of legumes over time. Re-seeding without plowing the soil is particularly common in mixed swards to maintain diversity over time. However, the impact of re-seeding on soils can be significant after plowing because this practice promotes SOC and nitrogen losses via mineralization processes ([Necpalova et al., 2014](#)). The periods of time over which

reseeding occurs can vary, but commonly swards are replaced every 25 years, and Liáng et al. (2020) calculated that plowing soils with this periodicity could result in annual carbon losses of $0.16 \text{ t C ha}^{-1} \text{ yr}^{-1}$.

Impact of different vegetation/species

Many pastures and silage systems have moved from mixed swards to monocultures of perennial ryegrass (*Lolium perenne* L.), sometimes with nitrogen-fixing white clover (*Trifolium repens* L.). Grass breeding has tended to favor the allocation of resources to above-ground biomass rather than root systems, meaning carbon inputs to many pasture and silage systems soils have been reduced. However, mixed swards with large species diversity have often been shown to be more productive due to their varied plant traits, indicating there is little competition between component species for the same resources under periods of stress. Furthermore, such swards can also increase soil carbon stocks (Lange et al., 2015). The introduction of legumes into pastures has been shown to result in increases in soil carbon stocks, due to the stimulation of both plant and microbial growth by the increase in available nitrogen from fixation by the legumes. More generally, increasing sward diversity has been shown to maintain and even increase soil carbon stocks (Lange et al., 2015). Diverse swards generally require re-sowing every 5 years, and as mentioned previously, this can impact on soil carbon, but it may also alleviate topsoil compaction, even though plow pans can develop deeper in the profile. Another consequence of plowing is that it regularly mixes the topsoil, potentially reducing heterogeneity in nutrient distribution established during grazing, whereas under permanent or long-term pasture systems this does not occur. Despite the fact that plowing can benefit sward establishment when reseeding, soil disturbance can result in changes in soil structure and promote mineralization processes (Necpalova et al., 2014), contributing to SOC depletion in the topsoil. The absence of vertical mixing in long term pastures is well illustrated in Fig. 5, in which a pasture soil, not plowed for approximately 80 years, has a stone free upper horizon of approximately 5 cm depth, resulting from bioturbation activity depositing soil that has passed through organisms such as earthworms and deposited a stone free layer at the surface due to the inability for earthworms to pass stones.

Silvopasture

The adoption of silvopastoral systems that integrate trees and livestock, ideally at low to medium density, can enhance biodiversity and provide a wide range of soil-based ecosystem services, such as the regulation of nutrients and water quality (Mayer et al., 2022). Moreover, silvopasture can be a sustainable option to reduce the footprint of livestock production by increasing carbon sequestration and reducing gaseous emissions. Feliciano et al. (2018) found that the greatest increase in soil carbon sequestration worldwide ($4.38 \text{ t C ha}^{-1} \text{ yr}^{-1}$) resulted from the transition of a grassland system to a silvopastoral system. However, in temperate climates, there is considerable variation in SOC sequestration rates in silvopastoral systems. Some studies have not found significant increases in SOC stocks after grassland conversion into silvopasture systems, even after several decades (Fornara et al., 2018). This is likely due to soil legacy factors, or limited potential for SOC sequestration because the soil was already at its maximum possible level. However, planting trees has been seen to increase more stable soil carbon fractions and micro-aggregates, improving ecosystem resilience (Baah-Acheamfour et al., 2014). Douglas et al. (2020) suggested that changes in SOC could be associated with planted species rather than silvopasture implementation. Therefore, a careful selection of tree species and areas suitable for silvopasture establishment need to be considered before any land management change.

Conclusion

Pasture, hay and silage can be produced on a wide range of soils and their productivity is affected by a combination of management, climate and soil type. In fact, the soil type often drives the type of management. Overall, the intensity of management tends to decrease in the order silage, pasture and hay, but it does not necessarily follow that soils under the less intensively managed hay systems are in better condition. This is largely due to the complexity of factors that interact in different soils. Despite there being some consistent differences in the way soils are managed under either silage, pasture or hay systems, the impacts on soil properties can be diverse under different conditions, demonstrating that management of soils is complex, as are soil systems in general.

Abstract

In dryland areas, production in agricultural and allied sectors is small and uncertain because of the scarcity of precipitation (<500 mm). Optimum utilization of resources (water, nutrients, forest, land etc.) is crucial to increase the agricultural output and improve the livelihoods of people living in dryland areas. Nutrition rich cereals, many traditional crops and large livestock populations are unique features of dryland ecosystems. For sustainable agricultural systems, efficient water management (in situ water harvesting, farm ponds, micro irrigation, hydrogels etc.), soil and land management (improving soil organic carbon (SOC), mulching, cover crops and biochar etc.), cropping practices (intercropping, conservation agriculture, tolerant crops and agro-forestry etc.) are critical.

Key points

- Climate variability in drylands areas
- Sustainable management options of dryland farming systems
- Soil degradation in dryland ecosystems
- Soil and crop management solutions in dryland areas
- Potential of dryland farming in different agro-ecological regions

Introduction

Drylands cover about 41% of the Earth's land surface with 38% of the world's population (Osman, 2018), which is distributed over approximately 6.1 billion hectares, and home to estimated 2 billion people, about 90% of them in developing countries (FAO, 2019). Most of the drylands are distributed in Africa (2000 M ha) Asia (2000 M ha), North America (760 M ha), Oceania (680 M ha), Europe (300 M ha) and South America (56 M ha). The majority of drylands are in continents like Asia (11 million km²) and Africa (nearly 13 million km²) (De Pauw, 2009). About 99% of the surface area of countries like Botswana, Burkina Faso, Iraq, Kazakhstan, Maldives and Turkmenistan is covered with drylands (Hori et al., 2011). The United Nations Convention to Combat Desertification (UNCCD) has indicated that drylands mainly occur in arid, semi-arid and dry sub-humid regions with an aridity index (AI) between 0.05 and 0.65. Drylands are classified into four types based on the AI as i) hyper-arid – AI <0.05, ii) arid – AI 0.05 to <0.20, iii) semi-arid – AI 0.20 to <0.50 and iv) dry sub-humid – AI 0.50 to <0.65. On the basis of the Aridity Index, 47.2% of the global land areas are drylands including: hyper-arid types ~7.5%, arid types ~12.1%, semi-arid types ~17.7% and sub-humid types ~9.9% (Hori et al., 2011). Different global land use systems in drylands are given in Fig. 1.

Drylands around the world encounter several constraints that limit crop productivity to a great extent. Most farmers in rainfed areas are small holders who have limited access to land, water resource, finance, market facilities, etc. Rainfed soils are usually coarse-textured and have small soil organic matter (SOM) content, low nutrient and water retention capacity, and multi nutrient deficiencies. As a result, crops grown in these soils result in inadequate yields. These lands are highly vulnerable to climate change because the agriculture sector is directly linked with climate that controls the rates of production. Crop production under moisture stress conditions presents a serious challenge to dryland farmers to achieve sustainability in crop production.

Problems in dryland farming

Climate change

Climate change in dryland regions is worsening soil conditions with prolonged periods of drought, accelerated desertification, and is reducing soil fertility by causing negative effects on biodiversity and vegetation cover – all of which undermine food and nutrition security. Climate change is gradually increasing the global area of drylands, estimates suggest that the area has already increased by 4% since 1948–1962, and by 2100 dryland areas have possibly increased by 11–23%, constituting up to 56% of the global land surface (Huang et al., 2017). By 2030, population growth linked with the expansion of drylands due to climate change might have increased the number of people living under challenging conditions by up to 70% (World Bank, 2017). The gap between farm yields and yield potential is small in developed countries like the European Union (EU) and USA (Global Yield Gap and Water Productivity Atlas), whereas in developing countries productivity is lower and the yield gap larger. Therefore, it is necessary to increase crop yields and stability over time via resistance and resilience to climate change. Increasing the temporal stability of crop yield is a major goal for smallholder dryland agriculture in the context of climate change.

Most of the countries in Africa already face semi-arid conditions that make agriculture challenging and climate change will be likely to reduce the length of the growing seasons and force large regions of marginal agriculture out of production. As per the research prediction model, it is suggested that climate change will reduce crop yields (specifically winter crops) up to 11% and 32%

Fig. 1 Different global land use systems in drylands (Osman, 2018).

by 2050 and 2080, respectively in India (Kumar and Sharma, 2022). and this may increase by up to 90% by 2100 (Kumar et al., 2019). Without increased resilience, up to 3.8 billion people across the climate-vulnerable global drylands will be deprived of their livelihoods if the effects of intensifying climate change continue as predicted (ICARDA, 2020). Even if climate change follows only the present estimated trajectory, 10% of the total agricultural economic value could be lost worldwide by 2050 (Swiss Re Institute, 2021). However, the impacts of climate change will be much more extreme in dryland ecosystems, where the economy, and food and nutrition security are inherently linked with agriculture.

Soils under dryland farming

Global dryland soils belong to several orders of Soil Taxonomy such as Entisols, Alfisols, Aridisols, Vertisols and Mollisols (Soil Survey Staff, 2022). Dryland soils are classified as Calcisols, Gypsisols, Steppe soils and Leptosols in the World Reference Base for Soil Resources (WRB, IUSS, 2022). Climate, vegetation and parent materials are the primary factors of soil formation in drylands. Precipitation, temperature and evapotranspiration are major components of the climate. Under dryland environments rocks and minerals can undergo physical weathering, whereas because of the lack of moisture bio-chemical weathering is limited. Dryland soils have some common features all over the world such as coarse to medium texture, low moisture retention, accumulation of salts, lime (calcium carbonate) or gypsum, small organic matter contents, low biological activity and weak soil profile development (Srinivasarao et al., 2009).

Soil degradation of rainfed dryland ecosystems

Globally, the biophysical status of 5670 million ha of land is declining, of which 1660 million ha (29%) have human induced land degradation. Global land degradation has increased by 5–10 million hectares per year (Stavi and Lal, 2015). An increase in land degradation due to the increasing frequency of droughts was recorded in the Sub-Saharan region of Africa from 1968 to 1990 by Ibrahim et al. (2015). The impending land degradation causes greater threats to crop production and livelihoods of the people in developing countries. There is a gradual increase in soil degradation in India, with estimates of about 147 million hectares (Mha) of land area that has degraded (Bhattacharyya et al., 2015). However, various organizations reported different values of degraded land area in India viz., 107.4 Mha in 1994 reported by the Ministry of Agriculture (MoA) and 146.8 Mha in 2004 estimated by the National Bureau of Soil Survey and Land Use Planning (NBSS&LUP). The process of land degradation has mainly been caused by the removal of vegetation in dry, sub-humid and semi-arid regions enhancing soil erosion by wind, which is dominant in arid regions (Srinivasarao et al., 2021). More than 70% of land degradation was due to water and wind erosion, and 15% due to salinity.

Climatic variation in drylands

Weather is always a major concern in dryland farming, climatic factors such as precipitation, temperature, humidity and wind determine the climatic conditions of an area. Variation in climatic factors is a major concern in all agricultural regions, but it is the dominant factor in dryland farming regions. Annual precipitation in semi-arid region ranges from less than 50% to more than 200% of the annual average, and crop yields vary from zero to three or more times the average (Stewart, 2016). There is clear evidence that global surface temperatures are rising, and this is a serious concern for dryland regions because there is little evidence of increasing precipitation. Therefore, these already dry regions may become even drier. Global surface temperature has risen by 0.08 °C per decade since 1880, and the rate of warming over the past 40 years has been more than twice that at 0.18 °C per decade since 1981. The April 2022 global average surface temperature was 0.85 °C warmer than the 20th century average and tied with the average surface temperature in April 2010 as the fifth highest of the 143-year record (<https://www.ncei.noaa.gov/access/monitoring/monthly-report/global/202204>). All three locations mentioned in Table 1 are semi-arid (Aridity Index 0.2–0.5), but the climates are very diverse and require completely different cropping systems and management. Amman, Jordan has a humid period during the winter months. Rajkot, India, also has a humid period during the summer when precipitation exceeds potential evapotranspiration. In contrast, in Bushland, Texas, potential evapotranspiration exceeds average rainfall amounts every month of the year. With regard to the growing days Amman (119 days) and Bushland (0 days) are classified as sub humid and dry, but Rajkot (96 days) is considered as semi-arid.

Table 1 Agro climatic characteristics of different dryland farming locations (Stewart, 2016).

Location	Precipitation (P) (mm)	Potential Evapotranspiration (ETP) (mm)	P/ETP
Rajkot, India	674	2430	0.28
Texas, USA	470	1880	0.25
Ammon, Jordan	417	1608	0.26

Table 2 Major dryland crops and cropping systems in various regions across the world.

Region/Country	Dryland crops and Cropping systems
India	Mung bean (<i>Vigna radiata</i> L.), Moth bean (<i>Vigna aconitifolia</i> Jacq) Marechal), Cowpea (<i>Vigna unguiculata</i> L. Walp), Cluster bean (<i>Cyamopsis tetragonoloba</i> L. Taub), Pearl millet (<i>Pennisetum glaucum</i> L.) and Sesame (<i>Sesamum indicum</i> L.) Crops: Pearl millet (<i>Pennisetum glaucum</i>), Sorghum (<i>Sorghum bicolor</i> L. Moench), Cluster bean (<i>Cyamopsis tetragonoloba</i> L.), Pigeon pea (<i>Cajanus cajan</i> L.), Cowpea (<i>Vigna unguiculata</i> L.), Sesame (<i>Sesamum indicum</i> L.) and Groundnut (<i>Arachis hypogaea</i> L.).
Nepal	Elephant foot yam (<i>Amorphophallus paeoniifolius</i> (Dennst.) Nicolson), taro (<i>Colocasia spp</i> (L.) Schott), cassava (<i>Manihot esculenta</i> Crantz), winter bean (<i>Vicia faba</i> L.), air potato (<i>Dioscorea bulbifera</i> L.), cush-cush yam (<i>Dioscorea trifida</i> L.f.) and brinjal (<i>Solanum melongena</i> L.), sugarcane (<i>Saccharum officinarum</i> L.), turmeric (<i>Curcuma longa</i> L.), ivy gourd (<i>Coccinia grandis</i> (L.) Voigt) and legumes
Pakistan	Wheat, maize, sugarcane, pulses and vegetables etc.
Australia	Wheat, grain legumes such as field peas and lupins, oilseed crops such as canola or sunflower (<i>Helianthus annuus</i> L.), pasture legumes such as subterranean clover (<i>Trifolium subterraneum</i> L.) and medics (<i>Medicago spp.</i>)
The Canadian Prairies and the U.S. Northern Great Plains	The traditional rotation of spring wheat-summer fallow has largely been replaced with rotations based on apulses, such as lentil (<i>Lens culinaris</i> Medik.), field pea, chickpea (<i>Cicer arietinum</i> L.), and faba-bean (<i>Vicia faba</i> L.), and oilseed crops, such as canola (<i>Brassica napus</i> L.) and sunflower (<i>Helianthus annuus</i> L.), which are commonly grown in rotation with spring wheat.
U.S. Central Great Plains	Crop rotation of winter wheat with summer fallow. Other crops rotated with wheat in the Central Great Plains include sorghum, sunflower, and proso millet (<i>Panicum miliaceum</i> L.).
U.S. Southern Great Plains	Winter wheat is commonly grown in rotation with grain sorghum and other dryland crops include maize, cotton (<i>Gossypium hirsutum</i> L.), and proso millet.
Eastern and Southern Africa (ESA)	Maize (<i>Zea mays</i> L.), sorghum (<i>Sorghum bicolor</i> (L.) Moench), wheat (<i>Triticum aestivum</i> L.), barley (<i>Hordeum vulgare</i> L.), teff, chickpea (<i>Cicer arietinum</i> L.), faba bean (<i>Vicia faba</i> L.), enset bean (<i>Ensete ventricosum</i> (Welw.) Cheesman) and coffee (<i>Coffea Arabica</i> L., <i>Coffea Canefora</i> L.), cassava (<i>Manihot esculenta</i> Crantz), millet (<i>Panicum miliaceum</i> var. <i>miliaceum</i> L.), beans (<i>Phaseolus vulgaris</i>), sweet potato (<i>Ipomoea batatas</i> (L.) Lam.), Cotton (<i>Gossypium hirsutum</i> L.), tea (<i>Camellia sinensis</i> (L.) Kuntze)

Dryland crops and cropping systems

There are many constraints that limit crop yields in dryland areas, and dryland farming will become increasingly important to produce adequate food and fiber for the ever-increasing world population. Water supplies for expanding dryland farming areas are becoming increasingly limited and more expensive to develop. Wheat (*Triticum aestivum* L.), barley (*Hordeum vulgare* L.), millets and pulses (Pigeon pea (*Cajanus cajan* (L.) Millsp.), Chick pea (*Cicer arietinum* L.) and Cowpea (*Vigna unguiculata* L.) etc.) are the major global dryland crops (Table 2). Wheat and barley are the most important cereal crops in the Mediterranean, where high temperatures and water scarcity restrict yield during grain filling (Jacobsen et al., 2012). In South Asia, cereals are cultivated in all countries except the Maldives. In Pakistan, 90% of the country's food grain production comes from rice (*Oryza sativa* L.) and wheat. Potato (*Solanum tuberosum* L.) is one of dominant crops in most dryland agricultural regions in China because the demand for water by potato during the growing season largely matches the seasonal distribution of rainfall and temperature. Dryland cropping zones in Australia mainly occur between the 300 and 600 mm rainfall isohyets. The Great Plains region of the United States and Canada is an area of widespread dryland crop production, with wheat being the dominant crop. In the dryland systems in Eastern and Southern Africa (ESA), maize (*Zea mays* L.) is the dominant crop and accounts for 60–70% of the total cropped area in Zambia and Zimbabwe and >90% of the total cereal production in Zimbabwe, Kenya, Malawi, Zambia and Mozambique.

Livelihood challenges in dryland ecosystems

In addition to crop production and productivity issues, there are several livelihood challenges in dryland areas which the farmers are having to face including small and fragmented land holdings, lack of resources, poor infrastructure combined with severe unemployment for most of the year.

Technological solutions for sustainable dryland farming

Most of the countries with malnutrition and famine around the globe are in dryland areas, and crop production in many of these countries is expected to become more challenging; these regions already have huge gaps in potential crop yield. Technology is the major driving force for agricultural growth. Improved technologies should result in increased gains in crop production which can be significant over time. Considering the costs and constraints of resources such as water, nutrients and energy, the genetic enhancements in crop characteristics and their productivity levels should be coupled with improved efficiency of inputs. This will be possible only by using the existing improved technologies and by developing new ones. With advanced management and

greater inputs of water and fertilizers in poorly resourced dryland areas their efficiency of use could increase together with enhanced yields by 2–5-fold. Specialized dryland management practices such as water harvesting and reducing soil moisture loss can increase yields by 5–15% on average across the semi-arid tropics (SAT) regions and reduce year-to-year yield variability (Fischer et al., 2009).

Water technology solutions

In arid and semiarid regions, potential evaporation is generally higher than precipitation and non-uniform in distribution, resulting in frequent drought periods during the crop-growing season. Furthermore, surface runoff usually results from the high intensity rains and dry soil surface that resists water infiltration. As the water shortage in dry areas is a recurring crisis, people need information on how to capture and use every available drop of water efficiently. Water harvesting is a method of water collection that has been applied historically in arid and semiarid regions where rainfall is either not sufficient to sustain good crop growth or where, due to the erratic nature of precipitation, the risk of crop failure is very high. Water harvesting is now being applied all over the world. As new water harvesting techniques have been developed, more regions are employing water harvesting to help offset pressures on existing water resources. In Asia, many communities have emerged and are thriving in spite of the harsh arid conditions, and their social life has evolved around water scarcity and indigenous water harvesting techniques. Water harvesting works by collecting rainwater and runoff from a large catchment area into a small target area. In Sri Lanka, policymakers have focused on alleviating seasonal water scarcity in the dry zone with large-scale storage tanks and inter-basin transfers. In Nepal, community management of water systems has been popular (Ariyabandu, 2008). Supplemental irrigation during mid-season droughts potentially increases and stabilizes dryland land crops by 30–40%. Among the many types of intervention, establishing farm ponds is the most important and promising technology in the integrated watershed management program. It also provides other environmental benefits. Farm ponds can have multiple uses such as supplemental irrigation through efficient methods of water application (drip and sprinkler irrigation), fish culture or duck farming integrated with poultry, and also protect from scarcity of precipitation. Farm ponds and check dams minimize the water stress at critical stages of crop growth, which can lead to an increase in crop yield and water productivity in dry regions (Fig. 2). These structures provide local water and ensure food security by enhancing crop productivity and climate resilience.

Farm ponds

Check dam

Fig. 2 Rain water harvesting structures (Rangareddy District, Telangana State, India).

Micro irrigation

In dryland regions, fertilizer-use efficiency is lower than that in irrigated agriculture mainly because of poor fertilizer and crop management practices, and water stress at critical growth stages. Efficient use of harvested water through pressurized micro irrigation systems is crucial for enhancing water-use efficiency (WUE) thereby achieving greater crop productivity in drylands. Of a total area of about 11.1 M ha under micro-irrigation in the world, the greatest coverage has been recorded in Asia and Oceania (5.6 M ha), followed by Europe and North America (2.5 M ha each) and Africa (0.4 M ha). Israel is a good example, it is a desert nation with water scarcity that has become a water surplus nation because growers have adopted micro-irrigation practices, especially drip irrigation that has reduced the water used for irrigation by about 75%. The area under micro irrigation in India is about 60.9 M ha which represents 8.1% of the total irrigated area in the International Commission on Irrigation and Drainage (ICID) countries; while Israel has 99.63% of its total irrigated area (0.23 M ha) under micro irrigation (Saxena and Ramana Rao, 2019). Dryland soils are severely deficient in bioavailable nutrients, and fertilizer application with irrigation is an important technological option for efficient water and nutrient management. Fertilizer-use efficiency through fertigation ranges between 80 and 90%, which helps to save a minimum of 25% of nutrients. Among different fertigation methods, drip irrigation systems provide 90% efficacy, sprinkler irrigation about 70–80% and conventional surface irrigation about 60–70% (<https://www.niti.gov.in/>). Nutrient losses through erosion can be effectively minimized by the fertigation technique, which significantly improves the WUE, water productivity, crop yields and livelihoods.

Hydrogel applications in water deficient areas

Hydrogels are synthetic polymers, able to absorb and hold water 80–180 times of their volume because their hydrophilic functional groups swell upon contact with water while retaining their structure. Application of hydrogels at 2 g kg⁻¹ improved the water holding capacity of sand from 171% to 402%, which reduced the irrigation requirements. Hydrogels increase water availability in topsoils and enhance field crop germination by 2–4 days, improve crop survival by 7.2–28.6% and also have positive long-term effects on water retention throughout the entire cropping season (Tibirkov et al., 2021).

Soil management solutions

Soils hold the key to productivity and resilience to climate vagaries in dryland agriculture. The potential limiting factors for productivity enhancement in drylands are the loss of fertile soil through erosion, depletion of soil organic matter, emerging secondary and micronutrient deficiencies, soil compaction, surface crusting, and loss of soil biodiversity. Many common agricultural practices, especially plowing, disk-tillage and vegetation burning, accelerate the decomposition of SOM which results in soils being susceptible to wind and water erosion (FAO, 2005). Sequestration and rates of decomposition of SOC influence soil structure and porosity; rate of water infiltration and water holding capacity; diversity and biological activity of soil organisms; and plant nutrient availability. However, recommended management practices (RMPs) like mulch farming, conservation agriculture, cover cropping, agroforestry enhance soil health and allow sustained agricultural productivity. These practices need to be promoted as contributing to soil, land and water conservation.

Land leveling

Land leveling mitigates climate change by reducing the demand for irrigation water and improving water-use efficiency and it also reduces farm machinery operating time by 10–15%. The latter reduces the time of tractor working hours by 3¼ hours ha⁻¹ compared with traditional plowing, harrowing and leveling. For every hour of use, tractors of 37,300–41,030 W power use 4.25 L of diesel and emit 2.6 kg CO₂ L⁻¹ of diesel. Laser land leveling technology increased the land-use efficiency in cropping by 3–6% when several smaller fields were combined into one larger field. It also increased WUE by 12–40%, fertilizer-use efficiency by 10–13%, and reduced methane gas emissions by at least 20% (Sander et al., 2014). Laser land leveling includes benefits such as saving land, water, and agronomic inputs, increasing yield, and decreasing postharvest losses. It also results in the saving of energy of 3.0–6.9 GJ ha⁻¹ and decreases emissions by 1151–1486 kg CO₂-eq ha⁻¹ in countries like Cambodia, Philippines, Thailand, Vietnam and India (Nguyen-Van-Hung et al., 2022).

Conservation agriculture

Conservation agriculture (CA) practices such as no-tillage or reduced tillage, mulching, cover crops and crop residue recycling can effectively maintain soil moisture, increase yield and income, and improve farmland ecosystems in dryland ecosystems. Intensive soil cultivation breaks down soil organic matter (SOM) resulting in the loss of soil organic carbon in the form of CO₂; thus contributing to the decline in soil health and climate change. The CA practices consist of reduced tillage practices, legume crops in rotations and retention of crop residue cover which contribute to holistic and efficient soil and land management systems. Recycling of crop residues (by avoiding residue burning) can act as soil cover and can reduce the loss of water and soil while adding many essential nutrients into the soil (Fig. 3) (Srinivasarao et al., 2015). In drylands of the USA and Canada, where crop production is limited due to lack of N use and soil water availability, conservation tillage with long term diversified crop rotations involving legumes and cover crops has helped to increase water storage, decrease soil degradation and enhance dryland crop yields. In dry

Fig. 3 Conservation agriculture with a maize (*Zea mays* L.)–Horse gram (*Macrotyloma uniflorum* (Lam.) Verdc.) system.

Mediterranean climates, CA improved yields by 20–120% compared to traditional tillage systems because of improved plant nutrient availability and soil moisture (Piggin et al., 2011). In Ethiopia, CA enhanced crop yields by reducing soil erosion and runoff with substantially enhanced soil organic matter contents (Oicha et al., 2010). Mulching insulates the soil and buffers it from temperature fluctuations in dryland ecosystems. Straw mulching is widely used for many crops, not only to reduce evaporation from the soil, but also to increase rainwater infiltration. It increased soil water storage capacity in the top 30 cm of the soil by 17% and grain yield by 14–41.8% compared to the conventional method in Nigeria (Adeboye et al., 2017).

China, Japan, and South Korea are the greatest users of plastic film mulch; they account for 80% of its worldwide use. In China, plastic mulching has enhanced wheat and maize production by 33.2 and 33.7%, respectively (Liu et al., 2014). Cover crops in dryland agriculture improve the storage of nutrients and water, which enhances soil organic matter contents and they are also used as a surface mulch. Incorporation of legumes as cover crops in dryland agriculture increases the yield, nutrient availability and available water content. Further, long-term legume incorporation results in improvement of SOC, microbial biomass, and increases the soil fertility particularly in light-textured soils of drylands. Leguminous green manure crops grown prior to wheat in China enhanced the wheat yield (13%) and water-use efficiency (28%), and maintained the soil water balance better than fallow–wheat crop rotations (Zhang et al., 2016). In some Australian drylands, N fertilizer is not applied for wheat crops, but is substituted by N-fixing legumes which provide sufficient N to achieve good wheat yields. In countries like Zimbabwe (SE Africa), grain yield was greater for millet grown following legume cropping compared with continuous pearl millet cropping. Crop residue recycling is one of the key components of CA. Crop residues improve the soil health status and supply the necessary elements to the plants. In dryland areas, crop residue burning in rice, cotton, pigeon pea, castor, chilies, turmeric and other crop systems is still common, and large amounts of vegetable and fruit biomass are not recycled. About 25% of nitrogen (N) and phosphorus (P), 50% of sulfur (S), and 75% of potassium (K) uptake by cereal crops are retained in crop residues, making them valuable nutrient sources. Crop residues of rainfed crops such as cotton, castor, pigeon pea and maize are chopped and left on the soil surface to act as a mulch-cum-manure (Srinivasarao et al., 2020b). In India residue burning contributes 0.05% to the total GHG emissions, and it is also detrimental for soil microorganisms, causing a huge loss in biomass, organic C, and surface water and also leads to the formation of hydrophobic soils. Converting farm residues into biochar through pyrolysis instead of surface burning and the addition of biochar with fertilizer nutrients improved yields of several rainfed crops. Biochar added to the soil also mitigated the conditions from mid-season droughts through enhanced water retention (Srinivasarao et al., 2020b).

Integrated nutrient management

The potential of dryland soil to produce good yields is limited by the widespread deficiency of micro and secondary nutrients such as Zn (zinc), B (boron), and sulfur, in addition to deficiency of macronutrients and organic carbon. The productivity of various crops in dryland soils of the semi-arid tropics (India, East Africa, Australia, South America) is limited because of the nutrient poor soils. The yield of various crops in dryland regions can be profitability enhanced with better management of natural resources, the use of chemical fertilizers, and organic amendments. Incorporation of organic matter either in the form of crop residues, farm yard manure (FYM), compost or vermicompost together with chemical fertilizers has been shown to improve soil structure, water retention capacity, and water storage capacity of the soil profile (Ranjith et al., 2018). Combined application of inorganic and organic fertilizers reduced total N losses (41.2%) and P losses (33.3%), prevented soil erosion, and helped to increase the macronutrient pool in soil for sustaining crop productivity on a long term basis (Bouraima et al., 2015). Balanced fertilization showed an increase of 3 to 31% in the productivity of water in cotton and groundnut crops. There are ample opportunities for farmers and stakeholders to reduce GHG emissions that are resulting from agricultural production by reducing external chemical

inputs and increasing the usage of natural manures that ultimately help in improving crop productivity and the quality of agricultural produce in dryland farming systems (Srinivasarao et al., 2012).

Crop management solutions

Crop management solutions are an important strategy to achieve higher yields and to avoid production losses in dryland farming areas. Farmers need to adopt a range of innovative and frontier technologies to maintain the demand for food and other agricultural products from the world's growing population. Some crop management solutions are given below.

Intercrops

Intercrops ensure better weed control, reduce disease and pest incidence, and increase and stabilize overall productivity. It can be regarded as a biological insurance against risks under irregular or aberrant rainfall conditions. Intercrops are climate friendly, improve efficient use of the land and help to improve food security across the world. Productivity of cereal–legume intercroops was often reported to be higher and more sustainable in rainfed dryland systems than cereal monocropping (Fig. 4). Intercropping systems are a common feature of small-scale farming throughout the tropics and subtropics of Asia, Africa and Latin America, and are believed to contribute up to 15–20% of global food production (Lithourgidis et al., 2011). However, they are not widely used in large-scale agriculture in developed countries. Inter cropping systems in Southern Australian wheat belt regions indicated that among the intercrop groups studied, 'Peaola' (canola–field pea intercroops in which 70% are intercroops) showed a 50% increase in productivity, and 'cereal–grain legume intercroops' showed a 64% increase in productivity over monoculture (Fletcher et al., 2016).

Foliar sprays

Under dryland conditions, lack of soil moisture hampers the absorption of fertilizers that are applied to the soil; foliar application of plant nutrients, however, overcomes these limitations. Foliar spray has a negligible effect on various soil factors such as soil pH, fixation of fertilizers to clay, availability of soil moisture, and on the rhizosphere (soil which attached around the roots). Furthermore, very small quantities of fertilizers are required for foliar sprays which reduces inputs. Foliar application of concentrated urea solution enhanced dryland wheat yield by 31% and cotton by 13–51%. In Pakistan, foliar applied nitrogen also resulted in greater nitrogen use efficiency, net return value: cost ratio and relative increase in income compared to fertilizers applied to the soil. In drylands, foliar application of nutrients may increase the yield and yield components by decreasing water and nutrient stress, and by increasing water and nutrients use efficiencies. Some precautions are required when applying foliar sprays because a high dose fertilizer may cause burning of plant leaves, foliar fertilizers have to be compatible with other agrochemicals like herbicides, and water use has to be optimized.

Tolerant crops

Tolerance to dry conditions is the most important and essential quality of dryland crops. Most of the plants vary in their ability to tolerate aridity, and yields under arid conditions are based on their degree of tolerance. Developing varieties that are tolerant to

Fig. 4 Maize (*Zea mays* L.) + Cowpea (*Vigna unguiculata* L. Walp) intercropping system. (Cereal+legume).

Table 3 Degree of Tolerance of different crops in Global drought conditions (Creswell and Martin, 1998).

<i>Crop</i>	<i>Degree Of Tolerance^a</i>
Corn (<i>Zea mays</i> L.)	1.0
Sorghum (<i>Sorghum bicolor</i> (L.) Moench)	1.5
Pearl Millet (<i>Pennisetum americanum</i> (L.) Leeke)	2.5
Common Bean (<i>Phaseolus vulgaris</i> L.)	1.0
Cowpea (<i>Vigna unguiculata</i> L.)	1.5
Pigeon Pea (<i>Cajanus cajan</i> (L.) R. Wilczek)	2.0
Mung Bean (<i>Vigna radiate</i> L.)	2.0
Cassava (<i>Manihot esculenta</i> Crantz)	2.0
White Yam (<i>Dioscorea rotundata</i> Poir.)	1.0
Mixta Squash (<i>Cucurbita argyrosperma</i>) K. Koch	1.5
Okra (<i>Abelmoschus esculentus</i> (L.) Moench)	1.5
Pomegranate (<i>Punica granatum</i> L.)	2.0
Cashew (<i>Anacardium occidentale</i> L.)	2.5
Date (<i>Phoenix dactylifera</i> L.)	3

^aRated from 0 (no tolerance) to 3 (high tolerance).

multiple abiotic and biotic stresses with stress-tolerant Quantitative Trait Loci (QTLs), genes and alleles in elite cultivars is an efficient way of achieving climate resilience and with easy access to farmers (Pathak et al., 2018). In rainfed areas, farmers should focus on crop diversification such as climate-smart, hardy crops (millets); and include more high-value fruit crops such as dragon fruit (*Selenicereus undatus* (Haworth) D. R. Hunt) and pomegranate (*Punica granatum* L.) in drought prone areas (Table 3).

Agroforestry

In dryland areas, a change from cultivation with no trees to agroforestry can improve the soil organic carbon stocks, which can help to mitigate climate change. Soil organic matter content increases when trees are included in agroforestry through the addition of litter both above and below ground, which increases soil microbial dynamics compared to monocropping systems in rainfed regions. Agroforestry systems are widely practiced in drylands worldwide. These practices are predominant in the drylands of Eastern and Central African countries like Tanzania, Uganda, Ethiopia, Kenya, northern Africa, sub-Saharan Africa and Asia. Agroforestry practices such as alley cropping of barley and forage crops under pistachio (*Pistacia vera* L.), olive (*Olea europaea* L.) and vineyards are practiced in Turkey (Gundogan et al., 2010). Agroforestry technologies in Israel are based on an improved version of an age-old tradition of redirecting floodwaters to plots surrounded by dikes or hand-dug pits in which trees or shrubs are planted. Improvement includes the incorporation of nitrogen fixing trees and food crops which contribute to both food security and ecosystem services (Israel 21C, 2016). This multifunctional land-use strategy needs increased attention from agricultural communities and policy makers because agroforestry is one viable way to sustain soil health.

Integrated farming system

In view of the decline in per capita availability of land, it is imperative to develop strategies and agricultural technologies that enable adequate employment and income generation, especially for small-holders (farmers with <2.0 ha of land) who constitute the vast majority of the farming community in dryland farming systems. Adoption of integrated farming systems that involve different components such as crops, livestock, poultry, fisheries, etc., is a powerful tool and holds the key to ensuring income, employment, livelihood and nutritional security for small and marginal farmers in dryland regions. Dryland farmers need to adopt resource conserving technologies such as crop diversification and recycling of farm waste. Improvement in productivity, fixed income and net growth in profit, balanced diet, recycling of farm residues and sustainable growth in agriculture are the main benefits of an integrated farming system. In a well-managed integrated farming system, nutrients in manure are returned to the soil where they are used to produce feed crops for livestock production. More than 90% of the total population of large and small ruminants are kept on mixed farms in South Asia. About 55% of China's population farm using integrated crop–livestock systems, which utilizes 83% of the total cropland, produces 90% of beef and mutton, and 50% of pork and poultry in China (Hou et al., 2008).

Dryland farming in India-case study

In India, around 51% of the total cultivated area is under dryland farming. It contributes about 42% of the total food production and plays a crucial role in safeguarding the country's food security. Dryland farming systems are complexed with a variety of cropping systems, agroforestry and livestock production. Almost 80% of cereals, 50% of maize, 88% of soybean, and 65% of pigeon peas and chickpea, among other crops, are produced by dryland farming in India. Overall, dryland farming in India produces 40%

of food and supports two thirds of the livestock (Srinivasarao et al., 2015). Soils of dryland ecosystems are generally poor in soil organic carbon (SOC) stocks because of high temperatures and low rainfall. The critical yield gaps for the major crops of dryland farming in India ranged from 0.1 to 1.2 Mg ha⁻¹ (Srinivasarao et al., 2013). The main soil types (Soil Taxonomy and World Reference Base classifications) are Inceptisols, Cambisols (95.8 M ha), Entisols, Umbrisols (80.1 M ha), Alfisols, Luvisols (79.7 M ha) Vertisols (26.3 M ha), Aridisols, Calcisols, Solonchaks (14.6 M ha), Oxisols, Ferrasols (0.3 M ha) and miscellaneous soil types (23.1 M ha). Alluvial soils occupy the largest area and the problems associated with dryland agriculture are not so acute in these soils. Problems are, however, encountered frequently in Vertisols and Alfisols, which are largely distributed in the north western, central and southern parts of India. Rajasthan, Maharashtra, Karnataka, Madhya Pradesh, Gujarat, Uttar Pradesh and Tamil Nadu are the principal states that produce most of the dryland crops. The average yields are quite small for cereals (coarse grains) at around 1954 kg ha⁻¹, and oilseeds and pulses ~1265 kg ha⁻¹ and ~ 806 kg ha⁻¹, respectively. The national annual average rainfall in India is 1200 mm, yet regional differences can be as high as 10,000 mm per year in the northeast and as low as 150 mm per year in the desert regions. In India the total micro-irrigation potential is around 69 M ha; drip irrigation systems provide 90% efficacy, sprinkler 70–80% and conventional surface irrigation about 60–70% (<https://www.niti.gov.in/>). The Government of India is supporting this technology at the large scale with several incentives (Srinivasarao et al., 2014) (Table 4).

In Indian agriculture, the role of institutions becomes more crucial as there are structural- and enterprise-specific constraints like high transaction costs, lack of market integration, and interlocking of output markets which only institutions and organizations can

Table 4 Different technologies used to improve water use efficiency of rainfed farming in India.

Recommended domain	Existing practice	Improved technology	Performance
Royalaseema Region, A.P. India Telangana	Flood irrigation in groundnut solo cropping Excess rainfall runs off and farmers are unable to collect it for use during dry spells.	Supplemental irrigation from farm ponds through sprinklers Farm ponds are constructed at the lower side of the fields with a capacity to store 100–200 m ³ of runoff per hectare.	Yield of groundnut increased by 25% Tomato as a test crop showed a payback period of 10 years with benefit:cost (B:C) ratio 1.5 and internal rate of return (IRR) 18.9%. Method is more viable and economical in <i>Vertisols</i>
Northern Dry zone of Karnataka	No in situ moisture conservation practices during <i>kharif</i> (monsoon) season resulting in soil erosion and low yield of <i>rabi</i> (post monsoon) crops	Making square compartments (0.15 m height) on the field to retain rainwater and stop soil erosion.	Increase in yield of <i>rabi</i> (post monsoon) sorghum, sunflower, safflower and chickpea with 40, 35, 38 and 50%, respectively. It also significantly controls runoff.
Northern Dry zone of Karnataka	No in situ moisture conservation practices in sodic medium and deep black soils resulting in soil erosion and poor yields	Gravel and sand mulching in sodic <i>vertisols</i> during summer	Practice gives yield advantage of 125% in groundnut, 214% in <i>rabi</i> (post monsoon) sorghum, 300% in sunflower, 300% in chickpea and 366% in greengram. Cost of sand application can be recovered within 2 years of cropping
Northern Dry zone of Karnataka	Fallow crop during <i>kharif</i> (monsoon) and cultivation of sorghum, sunflower and chickpea during <i>rabi</i> (post monsoon) resulted in splash erosion and high runoff in <i>kharif</i> (monsoon)	Cover cropping with quick growing species like sunhemp, greengram, cucumber and ridge gourd in <i>kharif</i> (monsoon) to reduce runoff and splash erosion.	With cover cropping in <i>kharif</i> (monsoon), yield advantage in various <i>rabi</i> (post monsoon) crops varies from 43% to 300% with a B:C ratio up to 5.47.
Northern Dry zone of Karnataka	Farmers make bunds up to a height of 0.45 m without any provision for a runoff outlet causing soil erosion due to upstream pressure.	Created inlet spillway arrangement for draining water to the next plot downstream.	Allowing rainfall infiltration into the soil profile making it possible for two crops even in drought years.
Northern Dry zone of Karnataka	Farmers depend on check dam or nala bunds for recharging the dug wells when they go dry.	Surface water harvesting and diverting into a defunct well through filter bed having different layers of sand, boulders, charcoal etc.	Normal size wells (5*5*10 m) can store about 0.4–0.5 million liters of water per year.
Malwa region of Madhya Pradesh	Soybean cultivated on flat bed system as a rainfed <i>kharif</i> (monsoon) crop resulting in either moisture stress or they are prone to water logging in black soils eventually decreasing yields.	Broad bed furrow system (BBF) of 105 cm width are made, soybean seed rate reduced by 25%.	BBF enhanced seed yield by 36% with B:C ratio of 2.53. BBF system helps draining of excess water and improves soil physical condition in black soil.
Scarce rainfall zone of Maharashtra	Fallow land during <i>kharif</i> (monsoon) and practice monocropping of sorghum during <i>rabi</i> (post monsoon) with one or two harrowings for weed control.	Ridges (20-cm height) and furrows (45-cm width) are made at the onset of monsoon to avoid soil erosion and increase soil water storage potential.	Conserves 45% more moisture, retains it for a longer period and increases <i>rabi</i> (post monsoon) sorghum yield by 53% with B:C ratio of 1.76.

tackle effectively. Institutions help small farmers by reducing transaction costs, managing or reducing risk, building social capital, enabling collective action, and or readdressing missing markets. Many institutional innovations are emerging that are successfully bringing farmers together to aggregate their small marketable surpluses. Village Climate Risk Management Committee (VCRMC), Agro-Advisory Services (AAS), Farmers' Producers Organization (FPO), Custom Hiring Centers for Farm Implements and Agricultural Markets etc. are major innovations which help farmers to collaborate. The Indian Council of Agriculture Research (ICAR) has developed more than 650 contingency plans for all rural districts of the country towards drought preparedness, and real time responses towards overall stability of rainfed dryland systems in the country. It covers field crops, horticulture, livestock, fishery and poultry resilient technology options to implement with location specificity and with the Union and State Governments together (Srinivasarao et al., 2020a). These successful experiences are shared with other SAARC countries and have been presented at the United Nations Framework Convention on Climate Change platforms towards climate change adaptation and resilient food systems.

Conclusion and way forward

Developing and implementing moisture conservation technologies are imperative for drylands to deal with national food security and climate change. There is a range of innovative solutions available to help farmers cope with climate variabilities. Some of these technologies proficiently increase the WUE and crop productivity; such technologies need more promotion through appropriate policy options. In general, farmers of dryland area depended on the narrower range of solutions for their livelihoods, thus they are more vulnerable to climate effects. If the most feasible and cost-effective technologies can be brought into their fields, it would contribute significantly to the overall development of dryland agriculture. Efficient rainwater management and its utilization, reducing soil erosion and managing soil health with sustainable soil management practices, legume intercrops and resource conservation practices play pivotal roles in dryland crop production. Governing bodies should focus on the vulnerable sectors of drylands to find out the most appropriate technologies and develop effective policies in order to bring sustainability in the dryland ecosystem. In addition, the promotion of farmer producing organizations (FPOs), village markets, value addition and processing, storage structures, market linkages, agri startup are potential systems for the sustainability of dryland ecosystems and food systems across the world.

Abstract

Crop rotation has been implemented since the early days of agriculture's history; however, it has changed over the years with systems being neglected in some regions, but also improved in others. In this chapter, the focus is on the history and current characteristics of crop rotation, what has been done to improve it worldwide, and how different climate conditions can affect it. In addition, the many benefits of crop rotation for different aspects of production systems such as yields, soil carbon sequestration, and pest control, are considered including some social-economic effects in various countries and regions.

Key points

- Crop rotation can underpin a sustainable production system.
- It can increase soil fertility and also carbon sequestration.
- Microclimate can affect the success of crop rotation.
- Pests and diseases can be suppressed by crop rotation.

Historic overview of crop rotations

Conceptually, crop rotation consists of the temporal alternation of different crop species cultivated in the same field (or group of fields) in a recurrent succession. This contrasts with the prolonged planting of the same crop types across years/seasons, i.e. the so-called monocropping or continuous monoculture cultivation practice. Crop rotation may also involve leaving the land fallow for a given season (or seasons), which might be used as pasture or just left bare.

Crop rotation has been used since the early days of agriculture's history, dating back to the predynastic Egyptian period (about 8500 BCE) and coming into use either by accident or by design (Britannia, 2022). In the past, farmers implemented crop rotation primarily based on their seasonal calendar, which gave them the traditional basis for their planting pattern. Over the years, the idea of crop rotation was developed further and consolidated primarily based on observed positive results in crop yields. In short, this occurs mainly because each crop releases or absorbs different nutrients, which helps to balance out eventual deficits and or surplus thereof in the soil.

Other historical reports, including biblical writings, also suggest that crop rotation was successfully used by the ancient Jews, Egyptians, Romans and Greeks (6000 BCE). There is written evidence of the recognition of the importance of crop rotations and also of putting specific crops on unique soil types during Roman times. Although Cato the Censor (second century B.C.) dedicated most of his writing on farming to the cultivation of grapes (*Vitis vinifera* L.) and olives (*Olea europaea* L.), he also discussed the importance of applying manure and of fallowing land before planting annual or perennial crops. His writings describe the importance of vetch (*Vicia sativa* L.), beans (several species), and lupins (*Lupinus* spp.) in helping to improve the soil or fertilize the land, and that cereal crops following these legumes benefited and produced higher yields. Varro and Virgil (first century BC) recognized the importance

of alfalfa (*Medicago sativa* L.), a deep-rooted perennial legume, in providing improved fertility for the crops that followed, and they recommended rotations, fallow periods, and specifically a bean (*Phaseolus vulgaris* L.)—spelt wheat (*Triticum spelta* L.) rotation. Pliny (first century AD) wrote extensively on farming, including crop rotations in the context of Italy and the Mediterranean region (Francis, 2005). Likewise, there are written records of the early effects of crop rotations and advice against the continuous planting of cereals in the literature from the Islamic era (8th–11th centuries AD) in the Iberian Peninsula (Bolens, 1994).

The benefit of crop rotation on crop yields has been reported by many researchers and farmers over the years. Chinese farmers have had success for millennia with the implementation of the well-known three-field system. Crop rotation was also a popular practice during the medieval and early-modern European periods. In England, the implementation by Sir Charles Townshend of the so-called 'Norfolk Rotation', with four different crops, usually barley (*Hordeum vulgare* L.)-clover (*Trifolium* spp.)-ryegrass (*Lolium* spp.)-wheat (*Triticum aestivum* L.)-turnips (*Brassica rapa* L.), helped the country's agricultural production to almost triple in the 18th century. Even before such periods, there is some evidence suggesting that in prehistoric Europe (probably during the Old Stone Age) a sequence of different annual crops and pastures was grown in rotation after land-clearing, but often followed by regrowth of the natural vegetation. This practice was also similar to the more familiar slash-and-burn or swidden agriculture, which is still practiced in some parts of the world, particularly in the tropics.

In the Middle Ages (5th to the late 15th centuries) before the Renaissance, there was apparently a reversion to crop-fallow sequences. There are limited reports of perennial pasture-grass plantings in rotation with cultivated cereal crops. The use of animal manure was prevalent. Perhaps the effects of manure applications were more apparent in a given year, if there were adjacent areas with and without manure, than the more subtle differences that were the result of rotation, the effects of which were not easily observed. In the seventeenth and eighteenth centuries, more organized legume-cereal rotations began to appear in reports from England. They often consisted of 2–4 years of vegetable or fodder crops, 1 year in legumes, and 1 or 2 years in cereals. Mixed farming with crops and livestock was prevalent, and the pastures and animal manure undoubtedly contributed to cereal yields. These rotation systems were taken to North America by early settlers from northern Europe.

Cropping diversity in many early systems included multiple species as well as crop rotations. In Europe, the small grains were often mixed cultures of cereal species that were used for grain and for fodder. The well-known maize (*Zea mays* L.)-beans (*Phaseolus* spp.)-squash (*Cucurbita* spp.) systems of Central America and Mexico as well as the intercrop and relay crop systems of maize-beans-potato (*Solanum tuberosum* L.) in the Andean Zone are examples of diverse mixtures that evolved over centuries as people selected these New World crop species (Francis, 2005).

With an emerging understanding of soil chemistry and the responses of plants to applied manures and other soil amendments, crop rotations in the first half of the twentieth century focused again on cereal-legume sequences (Francis, 2005). Such a simplistic rotation was almost entirely phased out, in particular in developed countries, after World War II when large supplies of synthetic nitrogen (N) and other multiple-nutrient fertilizers became the new 'normal'. The specialization in field crops, especially cereals, and disappearance of livestock from most farms further pushed the systems into continuous cropping or a very simplified 2-year cereal-legume rotation. Such changes confirmed that even though farmers were implementing crop rotation for many years, they did not know about its impact on the soils and in the environment. Only in the past two decades, with the growing interest in organic agriculture and more integrated systems, followed by the emerging concerns around the sustainability of agriculture in the mid-1980s, longer and more complex rotations have attracted public attention around the world again. This is particularly so in wealthy countries such as the United States and most of the developed European countries but often forgotten by developing countries. This is, however, particularly important for the latter group, especially those located in the tropical regions of the globe, where soil and climate conditions allow a more intensify farming system, and therefore the implementation of conservationist practices, such as crop rotation, is essential.

Development and current crop rotation systems worldwide

The current crop rotation systems vary considerably depending on climate conditions (as rainfall has an effect on crop production), production systems, and social aspects of the region. Cereal-legume rotations are among the most frequently used systems, dating back to before Roman times (Martinez, 2005), and they still provide the foundation for the design of most crop sequences today. Rotation among crops from different families is one of the most frequently used approaches today in the temperate zone (Francis, 2005). In areas of adequate rainfall, above 600 mm year⁻¹, a maize-soybean [*Glycine max* (L.) Merr.] rotation is prevalent in the Corn Belt of the United States Midwest (Sahajpal et al., 2014). In areas with lower rainfall, irrigation is used to assure a crop, and rotations are less common in these systems. A summary of the general types of crop rotations is presented in Fig. 1, showing the array of different levels of genetic diversity that have been exploited in farmers' systems across the centuries.

Rotating different varieties of the same cereal, rotating different cereals, and rotating cereals with legumes are all strategies to provide some of the soil fertility and plant protection benefits that come from diverse cropping sequences. More diverse are the sequences of summer-winter crops and rotations of pastures with crops, but most diverse of all are the annual-perennial sequences and combinations such as alley cropping. Alley cropping is characterized by planting rows of trees or shrubs to create alleys within which agricultural or horticultural crops are produced. The trees or shrubs provide additional valuable products as fruits, nuts, wood, or fiber (Soratto et al., 2022). Integrated crop-livestock systems are also a form of sustainable intensification of agriculture that relies on synergistic relationships between elements of plant and animal systems to bolster critical agroecosystem processes, with potential impacts on nutrient cycling, soil health, and resilience to weather anomalies (Reddy, 2016; Peterson et al., 2020). In these systems, annual crops are rotated with perennial pastures for animal grazing, and they are especially relevant for tropical

Fig. 1 Different types of crop rotation, crop-pasture rotation, and long-term perennial alternatives, showing the increasing genetic diversity of specific systems (from top to bottom). Adapted from Francis CA (2005) Crop rotations. In: *Encyclopedia of Soils in the Environment*, pp. 318–322. Elsevier. doi:10.1016/b0-12-348530-4/00253-8.

regions (Salton et al., 2014). While those crop rotation models are gaining popularity once again, current agricultural systems are still predominantly monoculture-driven, which often depend on aspects such as synthetic inputs, mechanization, irrigation, and fossil fuels. Such a model, nonetheless, has proved increasingly unsustainable, with several studies indicating rates of soil loss that are greater than its rate of formation, water pollution and its scarcity, also environmental damage, loss of biodiversity, and effects on human health (Francis, 2005; Salton et al., 2014).

The use of grassland in crop rotation has been shown to have a positive impact on production. However, it might depend on the type of grass used. Grasses have different resource uptake strategies known as acquisitive and conservative strategies. Acquisitive grasses have specific traits related to the more fast-growing species with quicker nutrient uptake and growth, while conservative grasses have a slower growth rate and lower rate of respiration (Reich, 2014). The implementation of these contrasting species in the rotation might also affect the productivity and sustainability of production because it affects the rate of nutrient uptake.

There are huge differences between sustainable production systems in the semi-arid tropics and semi-arid temperate regions, not only influenced by rainfall events, but also by the production system per se. For example, crop production in countries in Africa and Asia are in village units. This means that if the production system is not sustainable at some point, people make necessary changes in land use or even migrate to another region to start the system over again. On the other hand, production systems in Australia for example are characterized by being family organized so that if sustainability or profits are not achieved, the cropping practices change and possibly also ownership of the land.

In some parts of the world, crop rotation is often used in association with direct drilling. This is when crops are sown directly into the stubble without cultivation or preparing the soil after the previous crop and all crop residue is left on the soil surface. In Brazil, the direct drilling system has been increasing rapidly, especially in recent years. It is estimated that today the system with rotation covers more than 33 million hectares, that is, about 61% of the area with annual crops in the country (Fuentes-Llanillo et al., 2021). Farmers are advised to leave crop residues in the field to cover the soil properly and maintain or increase soil organic matter: a minimum of 6–7 Mg ha⁻¹ year⁻¹ for the subtropical high-altitude climate, 7.5–8.0 Mg ha⁻¹ year⁻¹ for the subtropical low altitude climate and transition between subtropical and tropical climates, and 10–12 Mg ha⁻¹ year⁻¹ for tropical climates (Canalli et al., 2019). One of many benefits of direct drill associated with crop rotation is the effect on soil temperature, because the crop residues help to maintain the ambient temperature which helps to avoid crop damage. For example, the crop rotation system in Brazil varies considerably because of the vast range of climate conditions over the different regions (Canalli et al., 2019). The use of crop rotation systems in the South Brazil is more favored because it is possible to produce summer and winter crops due to the ample and even rainfall distribution over the year, whereas in Central Brazil (with an almost total absence of rain between May-August) it is difficult to grow winter crops (as it requires a suitable microclimate or irrigated agriculture). The main crops grown in Central Brazil are those that increase the input of crop residues to the soil surface (Canalli et al., 2019). This requires that they have certain characteristics,

such as rapid development and increased drought tolerance (Salton et al., 2014; Possamai et al., 2022). Although crop rotation is an important system for many aspects including sustainability, the microclimate and climate conditions are a barrier in many regions to the success in implementing this system worldwide.

It is difficult to suggest the best system for the design a crop rotation system because as mentioned above several factors might have a great impact on the production. It is important to choose species and cultivars with high productivity and large C/N ratio which delays decomposition and provides a proper soil cover and/or initial straw supply. With technological advances and greater knowledge nowadays, the use of crop rotation could be improved considerably regardless of the type of soil, region and climate. The success of these production systems also depends on knowledge of the particular features of each region and environment, including climate and socioeconomic variables. Such aspects will influence the establishment of the most appropriate rotation and type of management to be used, which will ensure its benefits and minimize the risks for production (Francis, 2005; Peterson et al., 2020).

Potential benefits and drawbacks of crop rotations

Crop rotation can be considered one of the key factors on the path towards sustainable agriculture. In general, crop rotation strategies can contribute to a range of important benefits (Francis, 2005; Ouda et al., 2018; Renard and Tilman, 2019), including but not limited to:

- Soil organic matter increments
- Amelioration in soil physical, chemical, and biological conditions and consequently longevity of the agricultural systems, fertility, water availability to plants, and crop yields
- Reductions in costs related to synthetic inputs (including fertilizers, pesticides, and other agrochemicals, etc.)
- Enhancement to overall farming activities and timing
- Reduction in rates of erosion by wind and water
- Boosting of overall biodiversity
- New market opportunities
- Resilience of the agricultural systems against climate as a general risk, as well as economic risks
- Reducing risks from climate-change-related threats

Crop rotation can favor many of the above aspects, but it is important to emphasize that soil management practices are a crucial part of the success and or failure of the chosen crop rotation system. Choices of crop species, harvesting techniques, tillage practices, among others, need to be carefully considered because they can have synergies and/or antagonistic effects that might either add to or counteract the benefits. For example, reduced tillage often maintains more residue on the soil surface, reduces erosion, and conserves soil moisture compared with plowing and other intensive land preparation and cultivation methods (Fuentes-Llanillo et al., 2021; Possamai et al., 2022). The additional stored moisture opens up a farmer's options for crop rotation and increasing cropping intensity through the growing season. Catch crops of short-cycle legumes may be planted following a principal cereal grain crop, or a green manure crop planted contemporaneously with or following a cereal, in combinations often not possible in many locations without this additional moisture (Salton et al., 2014; Peterson et al., 2020). In addition, reduced tillage increases earthworm populations, slows oxidation and the breakdown of organic matter to increase the long-term nutrient supply to crops (Jordan et al., 1997; Possamai et al., 2022). Rotations of tillage practices that reach different soil depths can reduce the potential for soil compaction that leads to the formation of a plow or disk pan. Conversely, depending on the crops grown in the rotation, soil type, climate, among others, reducing tillage intensity may increase the risk of plant diseases and weed infestation, meaning that the success of one is highly dependent on the other (Ouda et al., 2018). Accordingly, rotating dissimilar crops may pose a challenge for the implementation of reduced tillage, because it might require the use of different pieces of equipment at different times of the year, potentially also increasing the costs. On the other hand, in some countries/regions, the rotation of some specific crops might only be possible after adjustments in tillage intensity; due to improvements in soil moisture as mentioned above (Francis, 2005).

Crop rotation might require a large initial investment, for example, in seeds and specific types of machinery, and in addition the technical knowledge, skills, and time required from the farmer. Therefore, despite the many benefits claimed for crop rotations, they cannot be regarded as a 'silver bullet' solution. Crop rotation must, however, be regarded as one of the many actions that together with others will help on the path towards a more sustainable agricultural future, where products are not the only goal, but other ecosystem services are also valued (Ouda et al., 2018; Peterson et al., 2020). With this in mind, below are some of the main benefits that crop rotations could deliver in terms of profit, soil condition, and sustainability aspects, which altogether may represent the general basis for the future of agriculture.

Soil carbon sequestration

A crop rotation and its duration are defined by a fixed schedule of different crops planted annually or over several years, which might also include pasture or grasses and or fallow periods, with a given frequency with which one of the above uses returns to the

same agricultural field, i.e. piece of land. The alternation of crops associated with the implementation of a wider diversity of main crops and pasture or grasses and or fallow periods, can lead to changes in quantity, as well as the quality, of soil organic matter inputs (above- and below-ground) (Canalli et al., 2019). Accordingly, many recent pieces of research have indicated that crop rotation could help to enhance the delivery of many ecosystem services including improved soil organic carbon (SOC) storage when compared to monoculture systems (Salton et al., 2014; Ouda et al., 2018; Zani et al., 2021, 2022).

Increases in the quantity and quality of soil organic matter inputs are also known to benefit other soil features that are critical to the success of SOC accumulation and eventually to carbon sequestration in agroecosystems (Salton et al., 2014; Ouda et al., 2018). It is important to highlight that in this text the terms SOC accumulation and sequestration have distinctive meanings and must not be used interchangeably. The former simply indicates that SOC stocks, i.e. the balance between carbon inputs and carbon losses coming from the soil are positive for a given piece of land. Carbon sequestration, however, must consider a much broader view, which will determine whether the balance between carbon inputs and all losses, including non-carbon sources (e.g. N₂O emissions) and other carbon losses not coming from the soil (e.g. through fossil fuels uses), is positive or not. For example, the consumption of fossil fuels used to produce fertilizers and to till the soil and manage crops emits carbon into the atmosphere and these emissions are discounted from the carbon accumulated in the soil. Continuous increments in soil organic matter inputs can have a positive effect on physical (e.g. soil structure, bulk density, aggregate stability, water capacity), chemical (e.g. nutrient cycling, electrical conductivity, soil fertility), and biological (e.g. macro-, meso-, and micro-fauna) aspects, all of which are services associated with soil quality (Jordan et al., 1997; Ouda et al., 2018). Improvements in overall soil quality (i.e. physical, chemical, and biological aspects) help roots to develop and grow better, which in turn can have a direct positive effect on SOC accumulation at different depths, i.e. shallow and deeper horizons (Salton et al., 2014; Zani et al., 2021, 2022). The soil organic pool, in turn, has a direct effect on properties such as soil fertility and biodiversity and nutrient cycling that are advantageous for ecosystem services (Albizua et al., 2015; Tiemann et al., 2015).

Soil organic carbon enrichments depend on the effects of the individual crops in the rotation, but as an overall rule the more crops in the rotation the greater is the potential for SOC increments. In crop rotation systems, the diversification of root functionality with an extensive, more fibrous, and deep-rooted system usually results in larger SOC stocks compared with monoculture (Crusciol et al., 2015; Triberti et al., 2016; Zani et al., 2022). Many studies have indicated a direct relationship between root biomass, rhizo-deposits, and microbes as sources of below-ground carbon (Kell, 2012; Hirte et al., 2018). The development of a dense root system may also lead to improved soil aggregate stability (i.e. improved soil structure), and favor the protection and stabilization of soil organic matter, which is key for carbon sequestration (Zani et al., 2021). In addition, different crops will add a distinctive amount and composition of crop residues to the soil either through above-ground as well as below-ground inputs, resulting in a wide range of carbon and nutrient supply. A promising crop rotation design for the purpose of SOC accumulation is the old well-known integration of arable crops with pasture systems. While the main aim of temporary grass-clover swards is to increase productivity, nutrient supply, fertility and to break potential disease infestations, research has shown that grass-clover and or alfalfa ley periods in crop rotations can also increase SOC, with a maximum potential close to 0.4 t C ha⁻¹ year⁻¹ (Chen et al., 2015; Assmann et al., 2017; Zani et al., 2022).

Whether a ley period is used for cutting for hay or livestock grazing can also have a direct effect on the potential SOC stock. In grazing systems, extra inputs might occur from forage residues and animal manure, together with potential stimulation or change in root dynamics, turnover, and exudates from the pattern of plant removals or defoliation by herbivores (Salton et al., 2014; Crusciol et al., 2015; Triberti et al., 2016; King and Blesh, 2018; Peterson et al., 2020). Nonetheless, from a carbon sequestration perspective, grazing ruminants might also increase greenhouse gas emissions and/or reduce land available for cereal crop production, which emphasizes the complexity of decision-making about crop rotation systems.

Ultimately, it is only possible to conclude that crop rotation systems will regulate the composition of carbon pools, their stability and/or decomposability. However, as mentioned before, while crop rotation could in many cases enhance SOC accumulation, agroecosystems consist of several other management practices (and soil features or characteristics) that will together with the crop rotation, regulate inputs and outputs and therefore overall carbon sequestration potential. To summarize, an integrated approach, considering direct and indirect effects (e.g. crop growth in the rotation, market prices, management practices, soil type and characteristics, and its effect on carbon inputs and outputs, i.e. through greenhouse gas emissions) is needed when it comes to the real potential of carbon sequestration in agroecosystems that use crop rotation systems (Francis, 2005; Ouda et al., 2018).

Fertility and yield

Crop rotation has been suggested as a strategy for improvements in soil fertility and consequently crop yields. In North America, regardless of the growing conditions, a more diverse rotation system resulted in an increase in maize yield of 28% (on average) over time. It was also observed that under unfavorable conditions, yield losses can be reduced by approximately 14–90%, which also depends on other factors such as weather and soil condition in the specific array of years of the rotation per se (Bowles et al., 2020). Even under a simplistic 2-year succession system, e.g. maize-soybean, there are indications of increased yields of the former of between 5% and 10%. Similar yield increases have also been observed in other cereals grown in rotation with legumes, for example, grain sorghum-soybean, where the latter showed an approximate 10% increase in yields (Francis, 2005; Bowles et al., 2020).

Crop rotation's positive effects on yields are often attributed to improved soil fertility that accrues from the combination of a cereal-legume sequence and the increased soil organic matter that improves soil quality. The benefits of crop rotation on yields are also reinforced with current advances in hybrids and varieties of major field crops, which can lead to increases in yields of ~10%

Table 1 Examples and mechanisms for crop rotation contributions to soil fertility and nutrient cycling.

Examples or mechanisms	Contribution to soil fertility
Cereal-legume rotation	Improves soil structure, texture, tilth, quality Increases water percolation, aeration, nitrification Increase N availability in the system Promotes more efficient nutrient and water use
Different root structures	Shallow-deep species exploit more water and recycle more nutrients Improve soil aggregation and structure
Legume-grass sequence	Increase soil organic matter, N availability, and reduces pests
Biennial and perennial legumes	Increase soil organic matter and N availability, manages weeds
Longer rotations and diversity	Improves soil quality, increases soil organic matter and biodiversity of agroecosystem
Pasture-crops sequences	Increases soil organic matter, improves nutrient cycling and use-efficiency, and reduces pests

Adapted from Francis CA (2005) Crop rotations. In: *Encyclopedia of Soils in the Environment*, pp. 318–322. Elsevier. doi:10.1016/b0-12-348530-4/00253-8.

(or more), particularly when part of a crop rotation system (Francis, 2005). However, other numerous improvements to the soil system can be related to improved yields in crop rotation systems. Several specific effects of crop rotations are summarized in Table 1.

Crop rotation's positive effect on yields is a consistent observation, even when all apparent nutrient needs of crops are satisfied and there are no obvious limiting pest and disease problems, which reinforces the benefits it might provide to soil. If there are serious limiting factors that cannot be remedied by other means, for example, a severe insect infestation or plant pathogen infection, crop rotations may increase yields even more compared to monoculture systems. The main reason for this might be because different plant species have different susceptibilities and strengths and as such, they might suppress the pathogen population and/or decrease the disease severity when used interchangeably (i.e. responding differently to stresses) (Ouda et al., 2018).

Crop rotation that combines cereal-legume sequences (e.g. maize-alfalfa) not only has higher yields than continuous maize, but the need for additional N is minimal in the first year. Equally, rotation of summer and winter crops, annual and perennial crops, and crops with pasture for grazing all reduce the need to apply fertilizers. In a rotation with soybean, this is quite common because it fixes much of its N requirements, and fertilizer is often not applied to this crop (Francis, 2005; Bowles et al., 2020). In general, the reduced need for fertilizers in crop rotation results from the rotation of crop root systems, patterns of nutrient uptake, timing and different nutrient needs, and diversity in crop residues.

The importance of growing N-fixing legumes in crop rotations is their ability to fix atmospheric N with their root nodules, leaving available N for the subsequent crops. In addition to its potential benefit to productivity, this has also been linked to a potential reduction of N₂O emissions if these N-fixing legumes are associated with other grass species compared to monocultures in grass-legume mixtures (Barneze et al., 2020). There is a well-known relationship between productivity and N₂O emissions, which has been proved in many studies throughout Europe (Moreau et al., 2015). The N available in the system can be taken up by plants which increases above-ground biomass, while decreasing the emissions. The use of crop rotation has normally been associated with a reduction of fertilizer application, which can also be linked to the reduction of N emissions from the system. On average, a farmer who implemented crop rotation with legumes can increase their yield by 20% (particularly in maize) while having a cumulative reduction of N₂O of 35% (Behnke et al., 2018). This is especially important because agricultural systems are now required to be increasingly sustainable to accord with current climate change mitigation.

Improvements to the soil system as a result of crop rotation can also explain the positive effects this system can offer in areas with less rainfall. Under such conditions, if wheat, for instance, is grown in rotation with a fallow year, enough soil moisture accumulates during fallow to make the crop profitable. An average of 25% of the fallow-year moisture is stored for a succeeding crop, with the rest lost to evaporation. However, this is sufficient in traditional systems to make the wheat-fallow rotation consistently profitable. Recently such systems as Eco fallow, with minimal tillage and a sequence of two crops in 3 years (e.g. wheat-proso millet (*Panicum miliaceum* L.), wheat-sunflower (*Helianthus annuus* L.), or wheat-maize) with short fallow periods, have intensified cropping and made better use of available rainfall. In dry climates, many reports have shown consistent improvements in yields by applying longer crop rotation systems (Tamburini et al., 2020). It is possible that rotating deep- and abundant-rooted crops could favor not only water use efficiency but also other soil system aspects, as for example, soil structure, water transport, which can be used for shallow-rooted cash crops, and the allocation or recycling of other nutrients such as potassium (K) and phosphorus (P).

Despite the potential benefits that crop rotation may offer to soil fertility and yields, there are also inconsistent observations in longer crop rotations. Beyond the two-crop succession system, such as maize-soybean, the inclusion of other annual crops is thought to be related to a potential suppression from the likely use of higher inputs and consequently adverse effects on the beneficial functions that crop rotation may offer in low-input systems. Such uncertainties make the implementation of more diversified crop rotation systems challenging in the current high-demanding intensive systems.

In summary, it is important to highlight that while crop rotation can improve soil fertility and consequently increase crop yields, it is difficult to eliminate completely issues such as water and nutrient deficits, weeds, pests, and/or diseases. This is particularly

questionable for more diversified crop rotation systems, where the benefits of crop rotations might be surpassed by adverse effects from unavoidable high inputs. Nevertheless, a crop rotation system that puts such aspects as the focus for its design can certainly lead to a significant decrease in dependence on synthetic inputs, which can sometimes even eliminate the continuous use of N and synthetic pesticides.

Pest control

The current changes in climate (temperature, rainfall, etc.) together with the occurrence of extreme weather events around the globe has indicated a potential increase in pest outbreaks and the need to implement strategies for preventing and/or improving crop resilience. Planting different crops in successive seasons or years can effectively disrupt the reproductive cycles of many weeds, insects, plant pathogens, or other pest species. As such, crop rotation has been recommended as a biological method for promising effective pest control (EU, 2009; Skellern and Cook, 2018).

The rationale behind crop rotation's effectiveness against pests is that there is no host available for crop-specific parasites because of the additional time within the rotation between the growth of the potential host crops (i.e. their life-cycle is disrupted). A well-planned crop rotation can decrease the potential for weeds, pests, and diseases to reduce crop yields and their quality, and can also diminish the costs of their control. One well-known and successful example of the use of crop rotation for such purposes is the organic crop production systems. Organic systems rely almost entirely on rotations plus genetic resistance to manage crop pests without synthetic pesticide applications. Problems with soil-borne pathogens such as bacteria, fungi, and nematodes can be reduced by crop rotations that include different plant species and/or various crop families (cereals, oilseeds, and legumes). If that is accompanied by lengthening the rotation cycle, a wider spectrum of the shoot and root characteristics, biological and chemical traits, and crop management, can be achieved, which adds ecological complexity and benefits pest control (Marja et al., 2021). Nonetheless, as highlighted before, crop rotation alone cannot be regarded as a 'silver bullet' solution and the organic systems are there to 'teach' us that this must be accompanied by other management practices, including promising new ideas such as priming the soil and the use of natural materials (e.g. pheromones) among others. Nevertheless, for some soil biotic pests, rotation is the most readily and perhaps the only economic way to control them (especially in developing countries and tropical regions). Several mechanisms or methods for pest control (including a few examples) are listed in Table 2.

Longer rotations that include annual and perennial plants, or crops and pasture, can provide benefits for both soil fertility and pest protection. Annual crops allow frequent cultivation that will often suppress perennial weeds. Perennial crops may provide year-long competition that shades out annual weed species. Crop and animal mixed farming and a sequence of several years of annual crops followed by perennial grass-legume pasture mixes and grazing help to diversify income sources, and in addition control many weeds and other pests that can become problematic with the continuous cultivation of annual crops. Rotations of different animal species in the pastures such as ruminants, sheep, pigs, poultry (although unlikely at the large scales), have different preferences for grass length, for example, and also make more complete use of available forage. This also reduces animal diseases that can become problematic (they can possibly become endemic) in the continuous grazing of animals in a small space. For example, goats will eat many weed species that are overlooked by other grazing ruminants, while chickens eat insect larvae from the manure deposits of larger grazers.

While crop rotations might help to control many pests and diseases, it is important to stress once again that its success will depend on other soil management practices such as seed treatments, seeding time, and tillage (as aforementioned), among others. Furthermore, there are still contradictions in the current literature regarding its effectiveness on weed control (Marja et al., 2021),

Table 2 Mechanisms of crop rotation contributions to plant protection against weeds, insects, pathogens, nematodes, and other biotic problems.

<i>Mechanisms or process</i>	<i>Contribution to plant protection</i>
Cereal-legume sequences	Favors different weed spp., facilitates chemical and mechanical control
Unlike crop sequences	Reduces soil-borne pathogens
Maize-soybean sequence	Controls maize stem borer (<i>Busseola fusca</i>), maize rootworm (<i>Diabrotica</i> spp.)
Vegetable-cereal sequence	Controls nematodes
Potato-legume sequence	Controls wireworms (several species)
Continuous plant cover	Provides competition with weeds
Legume cover crops	Competition with undesirable weeds
Alfalfa in crop sequence	Control of annual weeds, increased predators and parasites
Strip-cutting alfalfa	Increases insect movement, increases natural enemies
Diverse crops in sequence	Soil biology diversity, suppression of soil pathogens, facilitates weed control
Cropping diversity over time	Promotes soil microorganism biodiversity

Adapted from Francis CA (2005) Crop rotations. In: *Encyclopedia of Soils in the Environment*, pp. 318–322. Elsevier. doi:10.1016/b0-12-348530-4/00253-8.

which seems to be due to the lack of other soil management control methods rather than crop rotation per se. This further emphasizes the importance of delivering multifunctional agroecosystems where crop rotation together with other soil management practices are key factors that must not be neglected.

Biodiversity

It is already known that having a greater diversity of plants improves soil microbial biodiversity and consequently soil and water quality, but the impact of rotational crop diversity on soil biodiversity is not well understood. Studies that compared soils under monoculture with those under different crop rotations showed an increase of 33% in soil carbon in mega-aggregates that formed with the diversity of crops in rotations (Tiemann et al., 2015). This increase in soil C is associated with an increase in soil structural stability because the diverse crops in rotation improve the quality and quantity of residues going into the soil, favoring the diversity of microbial communities and their activities. With the increase of microbial activities in the soil, soil organic matter can be trapped in soil mega-aggregates. Furthermore, increasing the microbial activity per se under rotations can shift the microbial community by having greater abundance of fungi compared to bacteria (Tiemann et al., 2015). Fungi are known to have an important role in the development of stable soil structure by binding the soil particles. The formation of these mega- and micro-aggregates help to trap C and N in the soil. The implementation of crop rotation has been shown to have a great impact on the composition of the microbial community, which is associated with improving soil structure and boosting soil fertility.

The use of different crops in rotation can also improve or change soil biodiversity because of the diversity in residual root exudates and plant litter (also by altering symbiotic associations) from preceding crops; these provide C substrates for a range of soil microorganisms. Crops with different root systems improve soil structure by providing optimum conditions for the growth of both more diverse and abundant biological communities. This enhanced biological diversity might favor aspects such as resource use efficiency and temporal stability of agricultural systems (Tamburini et al., 2020).

Research has also shown that crop rotation increases the richness and abundance of soil macrofauna. An experiment in Zambia showed that a maize-legume rotation increased the soil populations of earthworms, millipedes and termites (Sileshi et al., 2008). The use of green manure or fallow after rice (*Oryza sativa* L.) also enhanced soil macrofauna in the rice cropping system in China. There are also indications that monoculture cropland areas in Australia, and North and South America could benefit from the use of crop rotation in terms of pollinator abundance for pollination as well as weed control (Tamburini et al., 2020). A recent global database showed that diversified farming systems, where crop rotation is regarded as a cornerstone practice, effectively contribute to biodiversity including positive effects on species from 33 taxonomic orders (spanning insects, plants, birds, mammals, eukaryotes, annelids, fungi, and bacteria) (Jones et al., 2021). This is crucial for the diversity and multifunctionality of agricultural soils and the delivery of many ecosystem services that it provides to society.

Social and economic aspects

It is important to note that the choice of which crop rotation to put into practice is influenced by a wide range of factors, including biological interactions and contributions to yield on the farm, relative prices of differently adapted crops, and potential for production and marketing from crop and animal systems. Farmers' potential to use rotations may also depend on the agreements in place with landowners. Further, political decisions in the European Union and United States on crop commodity support payments and promotion for global markets for some selected crops narrow the farmers' options. Farmers around the EU, in particular, have chosen (sometimes even forced) to change their crop rotation accordingly.

Political decisions in the Baltic countries to position themselves for entry into the European Union caused major changes in cropping systems during the 1990s, as farmers began to compete in a regional and global market and abandoned the guaranteed markets that were common under the former Soviet system. While this situation holds true for agriculture in most parts of the United States and European Union, for some countries or regions, especially in developing countries, market price is often the key factor affecting farmers' choice of crops in a specific rotation and/or even implementing a monoculture system. For example, if prices are attractive for cereals, farmers might choose a cereal rotation that comprises mainly wheat, maize, sorghum and barley. Conversely, if legumes and/or forage seed prices are more attractive, farmers might establish a rotation that includes different bean species and peas, for example, or extend the forage seed crop for more than a year.

While financial factors are expected to be the main factor affecting crop rotation choice in developing countries, some events prove, as has happened throughout history, once again to disrupt more stable markets in developed countries. A recent example is the current conflict between Russia and Ukraine, where the latter's capacity to export crops has been greatly affected. Russia, on the other hand, is a leading exporter of energy and fertilizers, as well as crops such as wheat, barley, and sunflower seeds, but its capacity to export has been reduced because of many international sanctions. All of these have a direct effect on farmers (and of course consumers) and the price of certain crops has increased markedly.

In addition to financial factors, there are also other elements, including the availability of machinery, personal needs, family farming traditions (including knowledge and education of the farmers), and/or certain site-specific peculiarities, that influence farmers' choices when implementing a crop rotation system. It is within this very complex economic, biological, personal, and

Table 3 Mechanisms of crop rotation contributions to economic and social consequences for farming systems.

Mechanism or process	Contribution to economic or social viability
Rotation of fields	Places uniform area in all crops each year
Diverse crops in rotations	Provides forages, cereals, cash crops, soil building
Sequences of pesticides	Avoids build-up of resistance of insects, pathogens, weeds
Different tillage depths	Avoids build-up of plow-pan or compaction layer
Range in crop-planting dates	Spreads labor needs, reduces equipment costs
Range in harvest dates	Reduces peak labor demand, reduces equipment costs, increase high prices window
Diverse array of crops/products	Buffers price changes in marketplace gives direct sales
Different skills, labor needed	Increases interaction with local community for labor

Adapted from Francis CA (2005) Crop rotations. In: *Encyclopedia of Soils in the Environment*, pp. 318–322. Elsevier. doi:10.1016/b0-12-348530-4/00253-8.

political framework that crop rotations must be discussed and where many farmers (depending on the country and region) encounter the main hurdles that may discourage its implementation.

Despite these potentially adverse aspects, it is important to emphasize that there are positive economic and social aspects that result from diverse plant combinations on the farm. Table 3 lists several direct economic benefits or those that will develop as a result of biological and other soil changes in fields over time.

The rotation of large fields or within-field diversity by annual strip-cropping systems will diversify farm income and protect against a weak market for a single commodity. Planting summer and winter crops, or annual and perennial crops, will spread the demand for labor and equipment throughout the year and optimize the use of the area (Soratto et al., 2022). Such rotations provide income at different times of the year. The diversification into more intensive crops and products provides the opportunity to use labor from other farms or nearby communities, perhaps in addition and opens new markets for direct sale.

Economic diversity can be enhanced by both crop rotations and the diverse products that come from the farm. If value-added activities on the farm or in the local community can make effective use of available labor when field operations are less intense, this strategy can increase farm income and return to investment. Crop rotations and diversity of products open new economic opportunities for on-farm sales or cooperation with neighbors in other direct sales options. A diverse farm is also attractive to visitors for educational programs, farm stays, hunting, and other creative ways to add value to the rural landscape and its natural resources (e.g. increase biodiversity of the agroecosystem and consequently its resilience).

Final remarks

Although economic rewards, consolidation, and specialization drove many farmers away from rotations in the latter years of the twentieth century, it is likely that cropping diversity and rotations will become more important in the future. Government subsidy programs that link payments to the conservation of soil, water, and other natural resources often stipulate field and farm diversity as conditions for farmers to continue to qualify for payments (although this does not seem to be a global trend yet). Organic farming regulations and subsidies in some countries specify the types of rotations that must be used for farmers to qualify. There is often a rule against continuous cropping of the same crop species and a requirement to include legumes in at least half of the years in a crop sequence (BIO Intelligence Service, 2010).

With increased costs of energy, the nutrients from green manure and animal wastes become more attractive and cost-effective. When animal manure from concentrated confinement operations becomes an excessive liability because of water-quality issues, there will be greater pressure from society and from regulators to use this resource and cycle it back into the crop production process. Diverse crop rotations provide multiple opportunities throughout the year to apply manure and compost back into production fields. There is a growing appreciation to design agroecosystems that can mimic the diversity of natural ecosystems so that they can maximize productivity and minimize negative impacts on the environment. Crop rotations provide multiple benefits to farmers and society and will become increasingly important in tomorrow's agriculture.

Abstract

Soils in organic farming develop differently from those in mainstream farming due to different farming practices including crop rotation and agronomic measures. For health, environmental and energy reasons, organic farming does not use a number of inputs that are common in mainstream agriculture or conventional farming. As a consequence, cropping systems need to be adapted to take over or compensate for the functions of the excluded inputs. This article summarizes the effects of organic farming practices on selected properties of organically managed soils. As farming practices are decisive for the development of soil fertility, we use them as an organizational framework.

Glossary

Conventional or mainstream farming Agricultural practice, defined by the production of a small number (three to four) of crops, together with one catch crop (*Sinapis alba* or *Phacelia tanacetifolia*), using only mineral fertilizer together with pesticide application and all at increased intensity, mainly inversion tillage.

Key points

- Organic farming excludes herbicides for weed control and synthetic pesticides against pests and diseases, industrial nitrogen fertilizers and some mineral fertilizers, and limits the nutrient and carbon input via animal feed or any fertilizer according to the carrying capacity and productivity of the site (see organic guidelines)
- High diversity of crop rotations and specifically the share of forage legumes positively impacts soil fertility indicators
- Intercropping, integrated as often as possible in organic systems between two main crops, and organic amendments also contribute positively to several soil fertility indicators
- While solid organic manure primarily strengthens diverse physical and biological soil characteristics, and provides low amounts of ammonium and nitrate nitrogen, liquid manures supply the crop with highly available nutrients, specifically nitrogen as ammonium ions.
- Controversially discussed are the impacts of different soil tillage combinations on soil fertility. The organic approach, combining shallow turning and mixing the soil with loosening deeper soil layers, seems to be beneficial for soil fertility, but the final assessment also requires an integrative analysis of soil type, climatic situation, combined crop rotation, share of forage legumes and quantity and quality of intercropping

- Weeds might compete with the biomass production of the main crops, but also make their specific contribution to soil fertility, e.g., root biomass and distribution, or nutrient uptake
- The role of root exudates of the diverse crop species and varieties is not yet sufficiently researched with regard to their contribution to soil fertility (e.g., SOM)
- There is insufficient knowledge of organic farming systems for (semi-)arid and (sub-) tropical areas
- More systemized long-term trials including diverse crop rotations, forage legumes, tillage systems and organic amendments under different pedoclimatic conditions are necessary to clarify open questions

Nomenclature

AMF	Arbuscular mycorrhizal fungi
BMP	Best management practices
C	Carbon
CEC	Cation exchange capacity
DM	Dry matter
FM	Fresh matter
MBC	Microbial biomass carbon
N	Nitrogen
OF	Organic farming
SOC	Soil organic carbon
SOM	Soil organic matter

Introduction

Thematic focus of the article

This article mainly refers to a selection of key literature informing about the effects of organic farming practices on biological, physical and chemical aspects of soil fertility. The majority of research findings are based on comparative trials with conventional farming.

Background and definition of organic farming

At the beginning of the last century, Organic Farming (OF) entered the agricultural debate. Since these early days, the main approaches to OF have focused on agroecological practices that placed more emphasis on agronomic measures (e.g., crop rotation, cover cropping, organic manure, bio- and mineral fertilizers) to manage soil fertility and less on external inputs. Pioneers in this context include Lady Balfour, Hermann Brauner, Sir Albert Howard, Ewald Könemanns, Hans and Maria Müller, Hans Peter Rusch, Rudolf Steiner and others. All of them highlighted a specific aspect of fertility management in OF, e.g., R. Steiner on the combination of arable and livestock farming and the role of bio-dynamic preparations, Sir A. Howard on the use of compost and H.P. Rusch on soil microorganisms. Notwithstanding this, soil fertility is at the heart of the thinking of all the pioneers, which is a key element in understanding OF approaches and practices.

Nowadays, OF builds on the basic principles of the International Federation of Organic Agriculture Movements (IFOAM), including health, ecology, fairness and care with several obligatory, recommended or facultative guidelines (Table 1).

Table 1 Obligatory and facultative practices in organic farming systems.

<i>Farming practices</i>	<i>Obligatory</i>	<i>Facultative</i>
Soil tillage—shallow inversion and deep loosening		x
Crop rotation rules		x
Forage legume integration		x
Preference for organic amendments		x
Limitations for nutrient import via fertilizers and feed quantity and type	x	
Exclusion of synthetic nitrogen fertilizer	x	
Exclusion of superphosphate, potassium chloride, and some other industrially produced fertilizers	x	
Exclusion of a large group of synthetic pesticides incl. herbicides	x	
Exclusion of quick lime; inclusion of carbonic and dolomitic acidic lime	x	
Exclusion of Genetically modified organisms (GMO)	x	

Elements of organic farming systems

As a result of the complex interactions between different system components, the soil fertility management in organic farming relies on a long-term integrated approach rather than the more short-term targeted solutions common in conventional agriculture. In this paper we refer to the most discussed practices for assessing the impact of organic farming on soil fertility: (1) crop rotation; (2) cover cropping; (3) tillage; (4) fertilizers; (5) soil pH regulation; (6) weeds.

Soil health and soil fertility

Soil fertility is defined as “the function of the soil to act as a mediator of nutrients, water and air for plants and edaphon (soil life)” (Ottow, 2011: 421). It is the results of physical, chemical and biological processes that lead to the release of nutrients, water, aeration and stability to the plant and edaphon (Ottow, 2011), as well as the absence of any substances that may inhibit growth. Biological processes drive the transformation of carbon and nutrient cycling, improve soil structure, and regulate pests and diseases. Soil characteristics of farming systems are: diversity, abundance and activity of microorganisms and the proportion of earthworms, and other soil organisms such as arthropods; quantity and quality of soil organic matter and its characteristics, including ratios and contents of C:N, lignin, polyphenols and tannins; a high potential to prevent nutrient leaching, the proportion of bio-pores, water infiltration rates and water holding capacity, and soil aggregate stability. As the analytical products of fulvic acids and humic substances in soils are in question, we will not refer to previous research in this field.

The effects of farming practices occur in different layers of soils. We distinguish plant production-based (cropping systems) and agronomic practices (Fig. 1), which differ according to farm specific practices but also between farm types (e.g., arable cropping system (stockless or mixed), or horticultural systems), which may have different implications for soil fertility.

Interaction between organic farming practices and soil properties

Impact of farming systems

While many reviews and results of field studies on soils refer specifically to single factors influencing soil fertility parameters, the investigations cited in this section are a selection mainly comparing the two farming systems as a whole—organic and conventional—with their effects on soil properties.

Soil organic carbon levels are indicative of soil health, carbon mitigation, and provide evidence of soil quality and functions. When comparing multiple conventional and organic long-term studies, several authors have found increased aggregate stability, decreased soil bulk density, reduced runoff and soil losses, and higher SOC content in organic farming due to greater organic matter inputs from diverse sources (Gattinger et al., 2012), indicating that soils in OF are less prone to soil crusting. Jacobs et al. (2018) mainly found more SOC closely related to crop yield, a result that contradicts the previous observations, as yields in organic systems are approx. 30% lower than in conventional systems. Meta-regressions could not precisely determine the drivers, but differences in external C inputs and crop rotations (e.g., clover-grass mixtures as integral part of organic rotations) are important factors.

Organic Guidelines	Agronomic interventions		Cropping systems interventions		IFOAM Principles		
	Tillage systems		Crop rotation systems				
	Intensive (medium to deep ploughing; several tools)		Diversity (in minimum seven main crops and in addition intercrops)				
	Extensive (conservation tillage; reduced tillage; no tillage)		Forage legumes (annual and multiannual legumes mainly with grasses)				
	Systemic tillage (intensive and extensive elements combined)		Intercrop (cover-, green manure-, forage-, mulch crops etc.)				
	Nutrient and organic matter systems		Field herbs / weeds

Fig. 1 Agricultural interventions of organic farming systems and their impact on selected soil characteristics.

Regardless of the farming system, a greater investment in SOC may store more nutrients, but also increases mineralization (steady state). Organic systems often show increased microbial biomass carbon, microbial biomass nitrogen, total nitrogen, greater total phospholipid fatty-acids and dehydrogenase, urease and protease activities than conventional systems, indicating higher biological soil fertility in OF systems. With greater SOC, the application of chemical fertilizers as well as supplemental irrigation could be at least partially reduced without having a negative impact on crop yields (Lal, 2020). It can be expected that better microbial performance in the organic system could lead to increased nutrient availability.

In comparative studies, soils in organic systems show the greatest ability to store and provide water to plant roots, quickly drain excess water and facilitate root proliferation (Di Prima et al., 2018). It is argued that the most relevant effect on the soil water balance is likely to be an increased water infiltration capacity depending on soil aggregate stability and bio-pores, as SOC content itself has little effect on the water holding capacity of soils (Minasny and McBratney, 2018). It remains an open question why a serious increase in water content in soils is rarely observed with a larger SOC content. One interpretation could be the immediate uptake of water by plants as well as the relocation of water to deeper horizons and to groundwater. A prerequisite for this assumption is that a more SOC increases aggregate stability and the proportion of bio-pores, thus optimizing the infiltration of water. If humus supply and soil cover via crops is high, as well as the majority of fertilizers are of organic material, and the application of mineral fertilizers is comparatively less than in conventional systems, an increased risk of nutrient leaching is relatively unlikely.

However, Williams et al. (2017) found a tenfold cumulative increase in water infiltration in a long-term experiment over 40 years in a temperate zone when they compared organic farming practices with green manure (OGM) and animal manure (OAM) to a conventional control treatment. They detected larger and more stable aggregates in the organic treatments, with the weight diameter of water-stable soil aggregates in the upper 15 cm depth increased by 50%.

There is ongoing debate as to why soil fertility and biodiversity indicators are greater on organic farms, but productivity is generally less (Ponisio et al., 2015). One example of factors explaining smaller yields is the reduced use of fertilizers, especially nitrogen, energy and pesticides. There is evidence that increased physical and biological fertility of soils in organic systems could lead to an approximation of crop yields of both systems under extreme weather conditions or that the organic system even outperforms the conventional approach (Lotter et al., 2003). Therefore, it is debated whether the yield gap between these systems could narrow with future climate changes.

Based on a number of reviews and reports on long-term trials with different soil indicators, it can be concluded that organic systems have positive effects on soil fertility in multiple ways. However, it is not always possible to determine which factor(s) of the system are the driving factors that explain the observed differences in crop yields.

A common explanation is that at the beginning of the growing season and in the following crucial growth phases, nitrogen availability does not follow the nitrogen demand of the crop in a timely manner due to soil biological processes. Other positive soil fertility properties do not compensate for this.

Impact of cropping systems

Crop rotation systems

Systems perspective

Crop rotations in organic farming differ from those under conventional farming mainly due to a greater diversity of crop species, the integration of forage legumes with grass mixtures, a larger proportion of cover crops, and to some extent, intercropping (Freyer, 2003, 2019). The approach to the design of crop rotations—i.e., the sequence of crops over time—includes a change in the family of the selected crop species from year to year, the succession of spring and winter crops (under tropical conditions also the change of long- and short-rainy season crops from different crop families), of humus reproducing and humus demanding crops, weed suppressing and weed sensitive crops, of large (e.g., alfalfa) and small water-consuming crops, a shift between deep (e.g., alfalfa) and shallow rooting crops (taproot vs. fibrous), and nitrogen-fixing with nitrogen-demanding crops (Freyer, 2003, 2019). There should be also more emphasis on the root exudates of the diverse crops used for intercropping. Long-term studies are the main source of evidence for the multiple effects of crop rotations on soil fertility in organic farming.

Crop rotations in OF take over many functions that are externalized in the conventional system and substituted by inputs such as nitrogen fertilizers, herbicides for weed control and other pesticides to control pests and diseases. It is recommended that, in OF, each crop rotation includes approx. 20–25% forage legumes, the share of root crops should not exceed 30% and cereals approx. 60%, and whenever possible cover crops should be included.

Effects of diversified organic crop rotation systems

Field experiments document a positive influence of diverse crop rotations on microbial biomass nitrogen, total carbon and total nitrogen (Lori et al., 2017) and appear to correlate linearly with the volume of 0.2–3.0 µm diameter pores (“protective” pore space), the multifunctional pore system and a decrease in soil bulk density. The improvement in soil quality is particularly evident in labile soil C and N pools, both of which are important for maintaining N fertility in organic systems and the ability to supply nutrients to crops (Delate et al., 2017). These diverse crop rotations combine species-specific root effects (e.g., type and extent of root structural impacts) to influence the individual mechanisms underlying a stable, crumbly aggregate structure and multi-functional pore system, as well as changes in physicochemical properties. Versatile crop rotations also influence microbial communities of the rhizosphere and the incidence of soil-borne pathogens, and lead to reduced incidence of pests and diseases in susceptible crops.

Forage legumes

In organic systems, the overall nitrogen budget depends primarily on forage legumes (including annual and perennial forage legumes), with biological nitrogen fixation between 80 and 500 kg N ha⁻¹ y⁻¹.

As SOC at soil depths from 30 to 100 cm accounts for 36% of the total, as established by a study in Germany, crops with large root biomass and exudate formation play a key role in determining the ability of organic farming systems to sequester carbon (Jacobs et al., 2020). They thus can compensate, to some extent, for the reduced aboveground net primary production in comparison with systems without forage legumes and driven by mineral fertilizers (Jacobs et al., 2020).

Forage legumes such as *Trifolium pratense*, *Medicago sativa*, *Desmodium* spp. or *Trifolium alexandrinum*, often grown as a mixture with diverse grass species (such as *Lolium perenne*, *Phleum pratense*, *Festuca pratensis*), are known to contribute to multiple ecosystem services that can influence overall system sustainability. Perennial legume crops, such as alfalfa, consistently increase soil organic carbon (SOC) content, showing higher levels of labile organic matter fractions, biochemical activity and aggregate stability (Tully and McAskill, 2020), and have more soil biota (earthworms, nematodes, bacteria and fungi) than conventional crop rotations.

Thus, a greater proportion of root biomass in the subsoil compared to annual crops (Fan et al., 2016), estimated at 3–6 t DM ha⁻¹ y⁻¹ compared to 1–3 t DM ha⁻¹ y⁻¹ for grass species, has a positive effect on soil SOC content, soil aggregate stability, soil water infiltration capacity, prevention of soil compaction and erosion through continuous soil cover and weed suppression. They alleviate structural damages in the subsoil through “biological drilling” (Cresswell and Kirkegaard, 1995), by greatly increasing the number of large pores (>2 mm) in the subsoil compared to continuous cultivation of annual crops and pastures. In another study, soils under organic management with an alfalfa-based crop rotation showed increased rootability, thinner roots and greater root density of succeeding crops compared to conventional rotations (Monaci et al., 2017).

Under tropical soil, climate and agricultural conditions—in addition to the two-year grass-clover or alfalfa-, forage legumes such as pigeon pea (*Cajanus cajan*), lablab (*Lablab purpureus*), desmodium (e.g., *Desmodium intortum*) and others improve the total N content in the uppermost soil strata in the long-term and increase soil organic carbon in the upper soil layer (Kumar et al., 2020). Grain legumes with large biomass production, such as mung bean (*Vigna radiata* L.) and lablab (*Lablab purpureus*), are most effective in improving the structure of a compacted heavy soil.

Intercropping

In our case, we define intercropping (cover crops; catch crops) as plants that grow between two main crops with different uses. Theoretically, these crops can serve as fodder for animals, as food crops, as feedstock for anaerobic digestion, as green manure for erosion control and from a biodiversity perspective, or as a pre-crop for cereals and root crops, which has a positive effect on soil fertility. Two types of sowing are of relevance:

- *Undersown crops*: Primarily white and red clover, mixed with grasses, are used as undersown crops, especially in cereals. The transfer of fixed nitrogen during growth in the shade of cereals can be expected to be small (Høgh-Jensen and Schjoerring, 1997). After harvesting the main crop, the clover grass mixture develops into a main crop or continues as an intercrop. When cultivated as an intercrop, it can be assumed that after a growth period starting in march under a winter cereal, and harvested in October or the following year before start of a summer crop, approximately 40–80 kg N ha⁻¹ of fixed nitrogen is available for the following crop and the biomass is between 1 and 4 Mg DM ha⁻¹, the latter with positive impacts on soil structure, biology and weed suppression. Relay cropping, defined as an undersown crop in a main crop at the end of the growing season to take advantage of water surpluses, allows multiple uses. The expected yields vary between 0.5 and 3 t DM ha⁻¹.
- *Blank seeding*: These crops are sown after a main crop and harvested before the subsequent main crop. They need a growing period of at least 6 weeks, up to approx. 4 months if they are not frost-resistant, or they continue to grow until the following spring. Clover mixtures can fix up to about 60–80 kg N ha⁻¹ if cultivated until spring of the next year.

The nutrients in the biomass can serve as an early and easily available nutrient source in spring, specifically in case of leguminous crop mixtures (Marcillo and Miguez, 2017). Other effects include a reduced soil erosion risk, improved soil aggregate stability through soil cover, a dense rooting system providing the development of bio-pores, as well as the uptake of nutrients that prevents their leaching, always according to the plant material characteristics, as well as soil and climate conditions.

The biomass production of intercrops depends on species characteristics, climate, soils as well as sowing date and duration in the field. The substantially greater importance of the roots of intercrops compared to the aboveground biomass for soil C processes is discussed by various authors (Ladoni et al., 2016). The effect of intercropping on SOC is controversially discussed. Some authors argue that the effectiveness of these crops for carbon sequestration, per se, is overestimated, while others found significant increases in SOC concentrations after several years, although intercropping did not show an overall impact on SOC concentrations over short time periods. Factors influencing these processes are the plant species, the total plant biomass, the age of the material, its C:N ratio, the proportion of polyphenols, lignin, and root exudates.

Intercrop diversity increases carbon input to the rhizosphere and soil microbial biomass in the soil and may also have allelopathic effects on pests, diseases and weeds (Bahadur et al., 2015). Mixtures usually produce a larger yield of root biomass than the pure stands and therefore have a higher potential for efficient soil exploration by roots.

Tree based systems

The literature on agroforestry and alley cropping is comprehensive, but only few studies are available that specifically address the effects in organic farming systems. However, from a systemic point of view, agroforestry and especially alley cropping, is a fundamental element in organic farming as it contributes to many ecosystem services that are necessary for the maintenance of the organic system.

The concept of agroforestry is based on the observation that higher crop yields are obtained at a certain distance from trees or in places where trees were previously grown, and hence a higher fertility of soils in such areas can be expected. Various field experiments and reviews on alley cropping systems in different climate-soil environments have shown the ability of prunings from several tree species to deliver sufficient nutrients to meet crop demands, except for phosphorus. Shrubs and trees in diverse combinations have multiple functions in such a system, including mitigation and adaptation to climate change (Reyes et al., 2021). Under organic farming conditions, the agroforestry species of importance are those that contribute to soil fertility and do not compete with the main crop for agronomic inputs, i.e., with tap roots, rich root biomass, limited water demand (drought resistance), and the ability to fix nitrogen. The often-deep-rooted systems enable the uptake of nutrients from deeper soil layers, creating bio-pores that are relevant as habitats for microorganisms.

Patterns of nutrient release from organic materials are partly determined by their chemical composition as well as by soil type and weather conditions. Leguminous biomass releases nitrogen immediately from leaf and thin young root material, unless they contain high levels of lignin or polyphenols. Litter and roots of both legumes and non-legumes immobilize or mineralize N, depending on the size of the C:N ratio, with mineralization being associated with a small ratio. Competition between trees and plants for resources is often argued over, but several studies report no significant competitive disadvantages for crop yields when yield is summed over the entire plot size (Yamoah et al., 1986).

Impact of agronomic measures

Tillage and nutrient management determine detailed aspects of cropping systems. Their fine-tuning is necessary for soil fertility. The interplay between cropping and tillage systems as well as fertilizer strategies are decisive for crop yield, while avoiding negative effects on soil fertility.

Soil tillage systems

Systems approach

The overall directive for soil tillage in organic farming is the shallow mixing but only partial inversion of the upper fertile soil layer from 10 to 20 cm depth, together with the loosening of deeper layers with a cultivator (Peigné et al., 2018). Using this approach, the aims are: (i) to avoid or limit mixing upper fertile soil layers with deeper less fertile soil layers; (ii) to prevent a compacted layer developing between upper and lower soil horizons; (iii) to loosen the subsoil and fertile upper soil layers to create optimal conditions for root and plant growth, but also to avoid soil compaction and erosion. Tillage modifies soil structure and crop residue distribution, which in turn affects the substrate availability for soil micro-organisms and their ability to break down soil organic matter and release nutrients for crop growth. Soil tillage is also a key management tool in organic farming to suppress weeds, pests and diseases.

In addition to this general directive, multiple combinations of tillage technologies are used—such as shallow inversion tillage and non-inversion minimum tillage, no-tillage and cover crop mulch-based systems, making a general assessment of the impact of “organic” soil tillage technologies on soil fertility challenging. Likewise, “deep” plowing encompasses a variety of tillage systems and techniques with different impacts on soil quality and soil functions, but most publications on field studies in OF lack a detailed description of the plowing technique, thus the interpretation of their impact on soil fertility indicators is limited.

Diversified soil tillage systems

The main positive effects of reduced tillage systems are the reduction in the risk of soil erosion, owing to more stable soil aggregates and a mulch layer over the soil surface. In addition, reduced tillage systems result in a more pronounced stratification of soil properties (e.g., SOC, microbial activity, macronutrients, such as phosphorus and potassium), compared with “deep” inversion plowing (Jacobs et al., 2020). However, SOC enrichment at the soil surface due to reduced tillage is offset, for example, by smaller contents deeper in the soil profile. The net effects are hotly debated, the relevance in relation to annual anthropogenic CO₂ emissions is small (Hunt et al., 2020). Reasons are that deep plowing might reduce the SOC in the upper layer due to less incorporation of organic matter, while in the lower layers organic matter is also enriched, which is not the case with reduced tillage. If trials only focus on the first 15 cm soil depth they ignore the development in the lower layers, which might lead to these controversial observations.

Reduced tillage is associated with an increase in earthworm species and activity (Peigné et al., 2018), shifts in microbial communities, increased survival of arbuscular mycorrhizal fungi (AMF) and less siltation due to higher aggregate stability and humus accumulation in the upper soil layer, in addition to a reduction in fuel consumption and required workload. The effects on soil are mainly observed in the upper layer. If both soil layers are analyzed, more SOC is observed in deeper layers when deep plowing is applied. In those cases, the positive effects on the soil biota are more evenly distributed between upper and lower soil

layers. Depending on the specific conditions prevailing, in some cases reduced tillage systems, in other cases more intensive tillage systems perform better in terms of their effects on the associated soil characteristics.

Most experiments on organic farming indicate yields are smaller in response to reduced tillage, but larger yields have also been reported (Peigné et al., 2018). The most important factors determining yield were reduced nitrogen supply and greater weed infestation under reduced tillage (Cooper et al., 2016). In cases where reduced tillage led to increased weed pressure and thus reduced yields, a solution could be found through the use of clover grass, a crop rotation of spring and winter crops and thus the possibility of integrating cover crops.

In the case of no-tillage, soil warming and mineralization is slower, while biodiversity and biomass of soil organisms are enhanced. The risk of weed infestation is also very high. Mulching to reduce weed pressure additionally delays soil warming. After years of no-till, consolidation due to natural soil settlement is to be expected. Thus, no-tillage can be an option, but is accompanied by several challenges. Compared with seed beds without residues (conventional no-till), improved drill designs, e.g., with mulch cover, might reduce weed pressure, increase soil moisture, aggregate stability, soil organism activity and, specifically in case of maize or soybean, also reduce the risk of siltation and erosion, and thus might become a feasible approach for the organic system. Yields are even greater in conventional no-till systems and therefore further technological innovations are necessary for the mulching system to contribute both to soil fertility and crop yield.

Each tillage system has advantages and disadvantages, therefore shallow inversion plowing and the two-layer plow, or shallow loosening and temporary deeper loosening of soils could be a compromise to maintain or enhance the positive effects on soil fertility without negatively affecting crop yield.

Nutrient and organic matter systems

Systems approach

In organic farming the idea of nutrient and organic matter application is to optimize soil conditions via the “feeding of soil organisms,” increasing carbon content and optimizing soil chemical, physical and biological conditions. In practice, this is the case when biomass-rich solid organic amendments are applied. A large proportion of these fertilizer-derived nutrients first undergo a mineralization or decomposition process by soil organisms before they are available to plants. In the case of liquid animal fertilizers (slurry and biogas-slurry) or organic commercial liquid fertilizers (organic industrial fertilizers; biofertilizers) based on food and brewery residues, urban and communal waste and others, the nutrients are offered directly to the plant roots in larger proportions.

Farmgate nutrient budgets show that results can vary greatly between farms and farming systems (arable with and without livestock, vegetable production, etc.) depending on the share of imported nutrients (Reimer et al., 2020). Although nutrient export is comparatively smaller from OF than most conventional farms, soil stocks of P, K and other macro and trace elements are reduced over time (Reimer et al., 2020). Only off-farm fertilizers (and feeds) that are qualitatively and quantitatively accepted by organic standards can be used to contribute to balancing the farm nutrient budget, i.e., offsetting nutrient deficits in the soil, whereas on-farm organic matter can be redistributed from field to field but does not compensate for nutrient exports at the farm level.

The nutrient export of nitrogen is balanced through N-fixation by legumes as well as atmospheric deposition, which in Europe can contribute annually in excess of 20 kg ha⁻¹. All other nutrients have to be supplied mainly from off-farm, depending on the results of the soil analysis, the nutrient balance, the site-specific ability of tap-root crops like alfalfa to mobilize nutrients in the subsoil, and further information on the state of soil fertility, e.g., via spade diagnosis.

Therefore, to maintain soil fertility over the long term, a strict strategy to ensure efficient use of on-farm available nutrients from soil nutrient stocks is required, including optimal on-farm nutrient cycling via organic matter, constant supply of organic matter to managed fields via forage legumes and cover crops, and limiting nutrient losses through erosion and leaching.

Organic fertilizers

Organic matter sources are diverse—crop residue, straw, green manure, farmyard manure, compost, digestates, or residues from food processing—and contribute differently to soil fertility. Organic manures positively influence the functional diversity of microorganisms in the soil. Organic manure also improves soil physical properties with a significant increase in soil porosity and hydraulic conductivity, and a decrease in bulk density. Farmyard manures of different qualities (fresh or in different composted stages) show positive effects on soil parameters like SOC, earthworms and aggregate stability.

In organic systems with animal husbandry, solid manure application can improve soil fertility indicators, although their direct contribution to crop yield is relatively small, due to the small proportion of ammonium and nitrate nitrogen. In the case of liquid manures, nutrient availability for crops is large, specifically that of ammonium nitrogen, and directly enhance crop yield. Relatively small quantities can be applied using rates of approximately 10–20 m³ ha⁻¹ according to the crop demand during the vegetation period, limit the risk of nutrient leaching. The contribution of liquid manure to crop yield greatly depends on the application technique and its capacity to avoid losses by ammonia volatilization.

Mineral fertilizers

In organic farming, most readily soluble synthetic mineral fertilizers are prohibited with the objectives of reducing energy inputs and of feeding soil organisms rather than plants directly. There is also the working hypothesis that product quality and product shelf life are negatively affected, if highly soluble fertilizers are applied. All forms of mineral nitrogen fertilizers are excluded by the organic farming guidelines, instead rhizobia bacteria from legumes take over the supply of nitrogen, accompanied by numerous other functions with positive effects on soil fertility.

After an analysis of the nutrient status of the soils, the nutrient balance of the farm and approval by an accredited organic farming certifier, the addition of mineral fertilizers is permitted. However, the philosophy of only applying mineral fertilizers that need to be converted by microorganisms is only partially fulfilled, e.g., highly soluble potassium sulfate is allowed.

Under organic management, soils with a low level of available P content (e.g., analyzed via P calcium acetate lactate extract) were often found (Kolbe, 2015), whereas a larger organic P (P_{org}) pool was observed than under conventional management. This pool is particularly important in grassland soil, less so under arable farming.

The main challenges for soil fertility in terms of providing adequate nutrients in quality and quantity for plant growth, is the non-adapted nutrient stoichiometry of the most commonly used base fertilizers—solid animal manures or composts and commercial industrial fertilizers (including mineral fertilizers)—as they do not match the crop specific demand. For example, cattle or poultry manure contain twice as much or even more phosphorus per unit compared to plant N and P offtakes. Also, the composition of liquid manures is closer to the nutrient stoichiometry of vegetative products. As a result, the use of soil nutrients is inefficient, leading to an inappropriate supply of nutrients in terms of timing and quantity, with the risk of nitrogen losses through gases and leaching.

Liming

The pH of agricultural soils must be within an optimal range to ensure an efficient use of fertilizers, i.e., nutrient storage and availability, biological nitrogen fixation, aggregate stability, and a pronounced soil life. pH values between 5.8 and 7.2 offer optimal living conditions for microorganisms. In the case of pH values that are below 5.5 the effective CEC is reduced due to the reduced cation buffering capacity. A further consequence of decreasing pH is the limitation of available molybdenum, which negatively affects the nitrogenase activity and biological nitrogen fixation.

The organic guidelines allow the use of natural lime, such as limestone ($CaCO_3$) or its transitional lithotypes like lime marl, crayon or calcareous marine algae, while quicklime (CaO) or slaked lime ($Ca(OH)_2$) (structural liming) are excluded (Table 1). The composition and abundance of most of the soil fauna is affected by natural liming, including fungi, bacteria, archaea, nematodes, earthworms, and microarthropods. The effects of natural liming on soil biota and biological processes vary significantly, but with evidence of positive effects (Holland et al., 2018). Structural liming (quick lime and carbonic acid lime (slaked lime or natural liming)) may have negative short-term effects on microbial communities, earthworm and coleopteran populations. Liming of acidic soils stabilizes the organic matter content and improves mineralization (Fageria, 2012). To what extent the continuous application of different types of carbonic acid lime can lead to partially similar effects of quicklime is not known. The extent to which the pH value in organic farming differs from that in conventional farming is also not yet known, although some results from long-term experiments do not indicate any significant differences (Rodas-Gaitan et al., 2022). Although in organic farming forage legumes contribute to a pH reduction, in conventional farming mineral fertilizer composition varies and therefore also their influence on soil acidity. In all systems, a continuous application of animal manure and compost could contribute to an increase in soil pH, provided the initial pH is less than 7.4 (Whalen et al., 2000).

With regard to soil physical characteristics, natural lime application can aid in fostering a favorable soil structure and aggregates by developing clay-humus-complexes, increasing the stabilization of organic matter in aggregates and thus reducing the risk of soil erosion and silting, while promoting soil aeration, water infiltration and a favorable thermal balance (Holland et al., 2018).

The type of liming and the composition with other minerals, elements and as well as the particle size play an outstanding role in low input systems, especially their effects on soil biota and crop yield, as confirmed by several authors (Li et al., 2019). Currently, there is a lack of research focusing on organic systems, e.g., in relation to the type and composition of liming. However, such research would be of great importance, as a better adaptation of liming strategies could contribute to a reduction of yield differences between organic and conventional agriculture.

Conclusions

Main findings

There is evidence in the scientific literature that the contribution organic farming systems to soil fertility in terms of biological (e.g., soil microbial activity, earthworm population, etc.) and some soil physical (e.g., aggregate stability) properties is relatively large compared to many conventional systems (Table 2). At the same time, at least in organic farming systems, there is a long-term threat to soil (chemical) fertility in terms of soil phosphorus and potassium status due to long-term depletion resulting from negative structural farm balances of these nutrients. Field experiments also indicate that under climate change conditions, the relative yield difference between organic and conventional agriculture could decrease.

Often it is not a single practice but the organic system as a whole that contributes to the physical and biological fertility of soils, while the exclusion or incomplete application of relevant practices (e.g., adequate recycling of nutrients lost in exported products or by leaching) can have negative consequences for overall biomass productivity and thus soil fertility. Consequently, if some key organic practices, such as consistent nutrient recycling, are not applied, the conventional system provides similar or better results on some soil fertility indicators. Recent reviews and meta-analyses have shown that organic farming systems have more soil organic carbon. However, it can be assumed that when comparing organic farms without forage legumes with heavier yielding conventional farms, the latter show greater SOC content, whereas integrating forage legumes into organic farms results in larger SOC values compared to conventional farms of medium productivity.

Table 2 Effects of organic farming practices on soil fertility in comparison to conventional systems.

Sector/practice	Comparison of organic with conventional systems
<i>Cropping systems</i>	
Crop rotation and organic fertilizers	• Similar to higher levels of SOC depending on yields and straw management in conventional systems and forage crops in the organic crop rotations • Less soil-borne disease • Higher microbial biomass C, N and activity, higher diversity of soil microbial community • Smaller bulk density, greater aggregate stability or stable, crumbly aggregate structure • Reduced soil crusting, greater share of multi-functional pore system • Less runoff, less soil loss • Greater enzyme activities (phospholipid fatty-acids, and dehydrogenase, urease and protease activities) • Similar or higher soil N mineralization potential • Larger share of labile organic N
Forage legumes	• Large root biomass and rhizodeposition; nitrogen input • Overall positive effects on physical, chemical and biological soil indicators
Cover crops	• Short term improvement of soil physical conditions, small long-term increase in SOC • Increased availability of nutrients for the following crops (mainly with legumes)
Herbs / weeds	• Diversification of insect habitats, root exudates, microorganisms, and nutrient decomposition
<i>Tree- and shrub-based systems</i>	
Hedges	• Important element of the organic farming system (erosion control, biomass production, biodiversity, habitat for beneficials, etc.) • Systemized data of different hedge types functionalities are missing
Alley crops	• Fundamental part of the organic farming system, but integration in practice is still limited • Positive effects on soil erosion reduction, SOC, and nitrogen if leguminous species are used; transfer of nutrients from lower to upper soil layers
<i>Tillage systems</i>	
Tillage	• Several trade-offs, no-tillage is partly critical due to the risk of increased weed pressure in the organic system and as a consequence reduced crop biomass/yield
<i>Nutrient and organic matter systems</i>	
Organic fertilizer	• Increase in SOC and positive effects on diverse soil biological and physical indicators • Risk of long-term imbalances in the soil due to an imbalanced nutrient stoichiometry of organic fertilizers compared to the demand of crops
Mineral fertilizer	• No mineral nitrogen fertilizer allowed • Biological N-fixation via legumes with multiple positive effects on soil fertility • Lower use of phosphorus and potassium mineral fertilizer reduces risk of nutrient losses
External inputs	• Lower use of external inputs leads to lower nutrient concentrations in animal manure • Nutrient balances of phosphorus, potassium and other nutrients tend to be negative
Liming and pH	• Not in general a specific characteristic of one or the other system • Besides liming, animal manure and compost could be of relevance for pH regulation

These findings underline that the combination of crop rotations, based on forage legumes and cover crops, together with application of organic amendments and a moderate-intensity of soil tillage, represent the most promising practices with positive effects on the different soil fertility indicators, but always require a detailed site-specific adaptation of the whole crop-technical system. Forage legume-based cropping systems play a key role as they provide large inputs of carbon below- and aboveground and nitrogen, and have multiple positive effects on soil biota and soil physical and chemical characteristics. Forage legumes are the strongest biological competitor against weeds, which, at least in arable cropping systems, are one of the most important biological regulating factors limiting organic crop yield. Cover cropping as a key strategy in organic farming systems has multiple positive effects on soil fertility, especially with legumes mitigating the effects of nitrogen as a yield-limiting factor. Depending on the length of the vegetation period of cover crops, seed mixtures and climatic conditions, they have different effects on soil indicators. Minor positive effects on SOC can be expected after several years of application.

The various soil tillage systems sometimes have contradictory effects on soil properties, weed and disease incidence, which affects the overall productivity of the cropping system. Systems with reduced or no-tillage (the latter is rarely established) applied on organic farms have led to a stratification of many soil properties with positive effects on soil organic matter and several biological, chemical and physical soil parameters, primarily in the upper soil layers, while the values of these indicators are reduced in deeper soil layers.

Differences between the tillage system impact on total SOC in deeper soil layers are not convincingly established and are probably of only minor relevance. Due to observed reductions in crop yield as a consequence of increased weed pressure, especially under more humid site conditions, reduced mineralization of nutrients and impairment of soil structure (compaction), reduced tillage has not yet become established on most organic farms. The regulation of soil pH to create an optimal pH range for

microorganism diversity and activity is fundamental to nutrient availability in organic systems. Less important for soils but more for crop yield is the relationship between nutrient availability and the mismatched nutrient stoichiometry of fertilizers according to crop demand.

Ways forward

There are some factors that influence crop yield levels with direct consequences for soil fertility. For future improvement of organic farming systems, a better understanding of the main yield-limiting factors in different regions, cropping systems and single crops is needed to identify approaches to improve the overall system productivity and performance. Possible yield-limiting factors are either weeds, pests or diseases, or the supply of nitrogen and sulfur, which tend to have short-term effect, while phosphorus, potassium as well as sulfur are likely to have a longer-term yield limiting effect, with negative feedback effects on the nitrogen balance by impairing the potential of legumes to fix nitrogen.

A higher yield level will also result in more crop residues, potentially increasing positive effects on soil physical and biological properties. A better understanding of how weed control can be improved using modern technologies to provide further options to reduce the overall intensity of tillage could also be useful to improve approaches to protect soil from erosion.

Improving the overall recycling rate of nutrients between urban centers and agriculture is also a major challenge to achieve more sustainable overall nutrient cycles in our societies and improve soil chemical fertility, not only in OF systems. Organic industrial fertilizers as well as biofertilizers (biostimulants) is a relatively new group of fertilizers, where knowledge on soil fertility and crop yield is limited and needs further research. The multiple effects on soil biota, which vary according to lime type and properties, may not be well understood and require further research to optimize soil quality and effects on crop yields.

By their very nature, changes in soils and productivity may occur shortly after the implementation of a measure or with a certain time lag, sometimes of an additive nature. They may be of long duration or affect soils only during the current growing season, or become relevant only if repeated over time. The manifold effects of agricultural practices on soil fertility only become visible after several years of their application or are subject to changes over time, which are also due to weather influences. Therefore, long-term experiments are needed to better understand the effects of individual practices on soil fertility.

A further challenge is the identification of multiple effects, for example: (1) interactions between cover crops, tillage systems and weed pressure; (2) additive effects of multiple technical interventions and fertilizer amendments on soil fertility; (3) effects of diverse organic farming practices on aggregate stability and water dynamics; (4) research on root exudates and their impact on the inhibition of seed germination and crop growth rate. It is therefore useful to distinguish between the components of soil fertility that change relatively slowly, perhaps over the course of a crop rotation or in some cases over decades, and the direct contribution of materials such as fertilizers and manures.

As more extensive conventional systems overlap with the organic system, a differentiation of both systems has its limitations. There is a great deal of variety and nuance in both systems, which requires a classification of farming systems to better understand the distinction between the organic systems themselves and in comparison to the various conventional systems.

Further research is also needed regarding a multipurpose use of our landscape for biodiversity, fiber, energy and tree or wood production. This includes the impact of photovoltaic modules as integral part of a landscape (e.g., instead or in combination with hedges), or the effects of production of crops under photovoltaic modules on crop growth, water balance, temperature, etc. There is also a need for further research of tree-based systems in relation to: (1) soil fertility; (2) competition of resources between trees or shrubs and crops and landscape water balance.

Currently, most of the literature on organic farming systems refers to temperate regions, and less to arid or (sub-) tropical conditions. Here, the need for research is very great and urgent due to the fact that climate change increases the risk to food security, while a better understanding of soil fertility under organic farming conditions could contribute to an increase in production, especially in regions with limited access to external sources such as fertilizers or pesticides.

Abstract

The main ecological functions of soil include nutrient cycling, carbon storage and turnover, water regulation, soil habitat, above-ground diversity regulation, biotic regulation, buffering, and transformation of potentially harmful elements and compounds. The optimization of productivity concomitant with maintaining beneficial soil conditions is determined by various factors, including the physical, chemical, and biological qualities essential for the sustainable production of plant biomass and food security. As favorable soil conditions are essential for delivering multiple ecosystem services, in this chapter, we discuss the various soil functions and correlate them with several effects of human activities, agricultural practices and land use systems for different soil types and climate zones.

Key points

- Soil conservation management practices improve soil conditions and productivity.
- Soil fertility and biodiversity maintenance reduce the impact of climate change on agroecosystems.
- Sustainable management is critical for soil structure maintenance and water purification and regulation.

Introduction

As a central interface between the atmosphere, hydrosphere, lithosphere and biosphere, the soil fulfills various functions (Brevik et al., 2015), including sustaining plant biomass and animal production nutrient and water cycling, carbon storage, buffering, and transformation of potentially toxic elements and compounds (Haygarth and Ritz, 2009), which turn the soil into an essential component of food security and, consequently, life on the planet (Rojas et al., 2016). Additionally, sustainable soil management promotes other essential environmental services, such as water quality, balance of atmospheric gases, and biodiversity (Fig. 1).

Biomass production

The soil has the capacity to supply nutrients and water to produce plant biomass for human use, providing food, feed, fiber, and fuel within natural or managed ecosystem boundaries (Sandén et al., 2019). Productive soils have sufficient and balanced nutrient levels and support plant growth through adequate physical, chemical and biological quality, humidity and temperature, and contain no toxic elements (Lopes and Guilherme, 2007).

In agriculture, the soil plays a critical role. Besides providing physical support for plant growth, the soil must have an adequate porosity for root respiration, water infiltration, storage, and availability, a balanced pH and essential nutrients to support biomass production. Soil particle size (sand, silt, and clay) distribution also influences the productivity by affecting the soil porosity, nutrient retention and availability (e.g., cation exchange capacity [CEC]). Additionally, topography (slope) and climate (precipitation and temperature) influence soil productivity through influencing weathering and erosion, and also affect plant growth and development. Vegetation type, microorganisms, enzyme activity, other soil organisms, and the amount of above- and belowground organic

Fig. 1 Soil functions related to soil quality. SOC: soil organic carbon; MBC: microbial biomass carbon; CEC: cation exchange capacity. Adapted from Lal R (2016) Soil health and carbon management. *Food and Energy Security* 5(4): 212–222, <https://doi.org/10.1002/fes3.96>.

residues are affected by climate. Increased production of organic residues results in high carbon inputs in humid climates, which promote nutrient cycling, soil aggregation, and structure resulting from, for example, increased microbial activities, which increase the soil's CEC (Karlen, 2005).

Even when nutrients and water are limited, soil fertility management can improve soil health and increase the primary productivity by enhancing nutrient cycling and the capability of water capture and storage (Foley et al., 2011). Soil productivity is the capacity of the soil to perform productive functions and to optimize yield through adapting different management practices. Soil productivity can be determined by measuring the difference between inputs (such as water, nutrients, genetic resources, and pest control) and outputs (production or crop yield). Soil erosion, nutrient extraction exceeding nutrient inputs, organic matter loss, acidification, salinization, flooding, and soil compaction are the primary causes of soil productivity loss. Erosion removes the soil surface layer, which is generally more fertile because of its higher biological activity and organic matter content (Karlen, 2005).

Minimizing soil disturbance, increasing plant diversity, and maximizing soil through management practices such as zero tillage, crop residue management, and the use of cover crops can improve soil health in agroecosystems by influencing biotic and abiotic productive soil components, that favor soil productivity (Miner et al., 2020), and thus, gradually increase soil organic matter content. Techniques reducing surface runoff, such as terracing and strip cultivation, contribute to soil quality maintenance (Karlen, 2005).

Since soil microorganisms are fundamental for nutrient cycling and have essential interactions with plants, management practices that favor the abundance and diversity of microbial communities can increase crop productivity, reduce production costs by reducing needs of mineral fertilizer and pesticide use, and promote sustainability in agroecosystems (Cardoso et al., 2013).

Nutrient cycling

Essential substances for plant life, i.e., necessary for the plant to complete its life cycle, are called nutrients. According to the elemental analysis, plants are composed of mineral and non-mineral elements, essential (nutrients) or not for the life cycle. Non-mineral nutrients are carbon (C), hydrogen (H), oxygen (O) and represent approximately 90% of the total elemental composition of plants and are obtained from water and air. Mineral nutrients are nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg), sulfur (S), boron (B), chlorine (Cl), copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), zinc (Zn), cobalt (Co) and nickel (Ni). There are other elements that are beneficial to plants but are not essential, such as silicon (Si), sodium (Na), cobalt (Co) and selenium (Se). Mineral elements represent about 10% of the elemental composition of plants and are obtained from the soil (Taiz et al., 2015).

Nutrient cycling is one of the ecosystem services provided by soils, and it is influenced by soil biological and physicochemical properties, agroecosystems management, and climate. Most nutrients needed for plants are provided through soils and need to be available when required. The factors responsible for soil formation and, consequently, for the availability of nutrients are: parent material, climate, living organisms, time and relief (topography). The factors climate and organisms (active factors) act together with time and relief on the parent material. The availability of water (rainfall) and temperature variations are the main climate elements responsible for the chemical and physical changes of rock minerals (parent material) (Weil and Brady, 2017).

Plant-absorbed nutrients return to the soil and are recycled through the mineralization of organic compounds present in litter or crop residues. However, since in agricultural systems, nutrients are removed from the system through harvests and the crop residues

remaining in the system might not have sufficient nutrients to meet the nutrient demand of the subsequent crop, nutrient replacement practices via application of mineral fertilizer or organic amendments and other corrective measures are necessary to supplement natural nutrient input (for example, nitrogen via biological fixation) (Schröder et al., 2016) to ensure that nutrient inputs and outputs are balanced in the long term.

The ability of soil to recycle nutrients is affected by the capacity of soil to receive and retain nutrients, to make nutrients bioavailable, and to facilitate the extraction and export of nutrients by crops (Schröder et al., 2016), processes that are influenced by soil properties including content of Fe^{2+} , Al^{3+} , and Ca^{2+} compounds, CEC, pH, micronutrients content (important for the symbiosis of rhizobia and legumes), parent material, organic matter content, texture, porosity, soil bulk density, drainage, water retention, microbial activity (important for organic matter mineralization), climatic conditions (temperature and humidity), and management practices in agricultural systems (Van Breemen, 1995; Delgado and Gomez, 2016; Schröder et al., 2016).

Plants take up nutrients (typically in the form of dissolved ions) from the soil solution. The ions adsorbed, precipitated as soluble salts, or available as mineralized organic compounds constitute the “labile nutrient pool,” which is in equilibrium with the soil solution. Labile nutrients added to the nutrients in the soil solution constitute the “bioavailable nutrient pool.” The balance of nutrients and exchange rates between the labile fraction and the soil solution is influenced by chemical (adsorption/desorption or precipitation/solubilization) and biological (immobilization/mineralization) interactions controlling the ionic activities of the solution and transport of nutrients to plant roots (Delgado and Gomez, 2016). Following absorption, nutrients are distributed among plant leaves, stems, and roots, and nutrients are returned to the soil through senescence, exudation, and leaching. Weathering of primary minerals, atmospheric deposition, groundwater supply, and other sources increase the soil nutrient content, whereas leaching reduces it (Van Breemen, 1995).

In tropical ecosystems, where temperature and humidity are higher, rock weathering is more intense (Weil and Brady, 2017). Under these conditions, the soils are deeper, more acidic and comparatively poor in nutrients and non-recalcitrant organic matter. On the other hand, in arid and cold climate conditions, weathering is less intense and the soils are shallower, with a greater amount of nutrients and organic matter.

In highly weathered soils, soil organic matter plays an important role for the cation exchange capacity (CEC), nutrient availability and contaminant filtering through sorption in organo-clay complexes. Soil microorganisms are responsible for the decomposition of organic material (including xenobiotic organic pollutants) and, consequently, nutrient cycling. As for the source of carbon, microorganisms can be grouped into autotrophs and heterotrophs. Autotrophic microorganisms produce their own food (reduced carbon) through photosynthesis and chemosynthesis. Heterotrophic microorganisms, on the other hand, need reduced carbon (organic compounds) for their metabolism (Bollag and Stotzky, 2000). This way, microbial heterotrophic metabolism (decomposition of organic materials) regulates essential processes for maintaining life on planet, such as nutrient cycling and the ability to retain and exchange cations and anions in the soil.

Maintaining adequate contents of soil organic matter is essential for nutrient cycling. Thus, in cultivated areas, conservation management practices (e.g., no-till) should be encouraged. On the other hand, at least in the short term, the addition of organic materials to the soil can stimulate and accelerate the mineralization of the soil organic matter. When adding organic residues, there are intense short-term changes in the mineralization of soil organic matter - positive priming effect. In contrast, the delay in the mineralization of soil organic matter due to the addition of organic materials is known as the negative priming effect (Kuzakov, 2010).

Degradation of organic substrates results from several sequential chemical reactions mediated or catalyzed by enzymes (e.g., ligninases, cellulases, proteases, glucosidases, galactosidases, phosphatases, amidases, urease, sulfatase) that play a fundamental role in ecosystems, acting as catalysts for several reactions that result in the decomposition of organic materials, nutrient cycling and formation of soil organic matter (Tabatabai, 1994). This way, all biochemical transformations on the planet are also dependent on or are related to the presence of enzymes.

Climate regulation and carbon sequestration

In general, the soil is considered the largest reservoir of terrestrial organic carbon (C), storing two times the mass of C present in the atmosphere and three times the mass of C in the biota that live on the land surface (Lal, 2018). By holding this huge carbon stock, the soil plays an important role in climatic change mitigation.

The soil ability to regulate the climate is determined based on their potential to take up nitrogen from the atmosphere, promote C sequestration, and the reduction of greenhouse gas (e.g., CH_4 and N_2O) emissions (Van de Broek et al., 2019). A positive balance between soil carbon inputs and outputs allows the soil to function as a carbon sink, enabling improved climate regulation and sustainability (Shovik et al., 2015).

The soil C sequestration - the process of transferring carbon dioxide (CO_2) from the atmosphere into stable terrestrial C pools that are not re-emitted back into the atmosphere - is influenced by climatic factors (rainfall and temperature), soil texture, mineralogy, amount of crop residues, and/or addition of organic inputs, as well as by the management practices adopted by farmers (e.g., no-till).

Clayey soils generally have a greater potential for C sequestration than sandy soils, due to the influence the clay on organic matter stabilization processes impacting the longevity and persistence of SOC (Schmidt et al., 2011). In clay dominant soils the chemical adsorption of C onto the surfaces of clay minerals and the physical occlusion within microaggregates reduce the access of soil microbes to organic C (Sissoko and Kpombrekou-A, 2010).

Diverse mechanisms including electrostatic bonding, van der Waals force, hydrogen bond and coordination with oxyhydroxides and silicate clays are associated to the C absorption in clay minerals. The properties of the organic compounds, as well as the type of clay, the soil acidity and moisture can result in different mechanisms occurring at the same time.

Conservation-oriented soil management can contribute to the reduction of greenhouse gas emissions and the increase of CO₂ sequestration, which results in improvements in soil fertility and biodiversity, reduction of erosion processes and water pollution. These positive effects can help to reduce the impacts of climate change on agroecosystems (Smith, 2012; Paustian et al., 2016) in the long-term, even though the organic carbon present in the soil is highly dynamic. For example, the formation of stable microaggregates and organomineral complexes can promote the protection of organic carbon from microbial processes for millennia (Lal, 2016).

Several management strategies can be used to increase carbon inputs in agroecosystems, such as the use of species with deeper and larger root systems, crop rotations, use of cover crops, irrigation in places with water deficit, fertilization in soils with nutritional deficits to increase crop productivity, and use of perennial crops to minimize soil disturbance. Less intensive soil tillage, such as zero tillage, has been shown to promote carbon sequestration (Bai et al., 2019; Lee et al., 2019) by favoring aggregation and aggregate stability which is considered as the main mechanism promoting increased C (Lal, 2016; Van de Broek et al., 2019).

Water purification and regulation

Water purification and regulation is the ability of a soil to remove harmful compounds from water and the capability of the soil to receive, store, and conduct water, thereby contributing to the maintenance of high surface and groundwater quality, prevention of droughts, floods, and erosion, and food security maintenance and climate change mitigation (Wall et al., 2020).

In general, excessive use of agrochemicals can contaminate the soil and lead to the pollution of water resources. Additionally, land use change and degradation of agricultural lands can alter water quality through soil erosion, dissolution, and leaching of nutrients and other pollutants. However, through processes, such as precipitation, adsorption, desorption, ion exchange, oxidation-reduction, and metabolic decomposition, the soil can remove many soil pollutants favoring the remediation of natural ecosystems and agricultural lands (Cheng et al., 2021).

The ability of the soil to regulate water storage is influenced by environmental characteristics (e.g., precipitation volumes, frequency and intensity), soil chemical and physical characteristics (e.g., quality and quantity of organic matter, pH, type of clay minerals, and bulk density), and agronomic practices. Organic soil amendments and the adoption of practices that result in soil surface cover affect positively the water regulation function of soils by enhancing physical and hydraulic properties in soil, including soil porosity, bulk density, saturated hydraulic conductivity and aggregate stability (Jian et al., 2020). The surface cover protects the soil structure against degradation resulting in surface sealing, can increase the soil organic matter contents (Poeplau and Don, 2015), microbial biomass, community composition and biological activity, processes that promote stable soil aggregation, reduction in soil bulk density, increases in soil porosity, which in turn improves the flow of water and solutes in soil (Blanchy et al., 2023).

The conservation and improvement of soil structure are essential for the performance and maintenance of soil quality and water retention (Rabot et al., 2018). Soil structure is the spatial arrangement between mineral particles and soil organic matter and the arrangement and size of the pores between these particles, considering its stability against external forces (e.g., machine traffic and raindrop impact). Soil structure is considerably altered by soil management practices and cultivation techniques, which can modify the soil water holding capacity as well as water flow (Delgado and Gomez, 2016).

Total porosity, macroporosity, and connectivity between soil pores are also important indicators of soil structural quality, and can be used to assess soil functions and the several processes that occur after agricultural operations. Desirable values for the aforementioned indicators are generally positively correlated with large biomass yields, adequate water storage and filtration, nutrient storage, recycling, carbon storage, favorable habitat for a greater diversity of soil organisms to develop and perform their activities, and provide adequate soil physical support (Rabot et al., 2018).

Functional and intrinsic biodiversity provision

Soil biodiversity is critical for the maintenance of ecosystem services, and is controlled by a combination of environmental, biological, chemical, and physical processes (Thiele-Bruhn et al., 2012). Soil biodiversity comprises a multitude of organisms and processes interacting with an ecosystem that supports life above ground (Van Leeuwen et al., 2019).

Soil fauna (bacteria, fungi, protists, and invertebrates) is directly related to several ecosystem functions, such as nutrient cycling and storage, formation and turnover of soil organic matter, decomposition, crop production, reduction of pathogenicity potential, pest control, and increased resistance and resilience to the effects of extreme weather conditions. Therefore, the increase in soil biodiversity increases plant diversity in biomes and the self-regulatory capacity of agricultural and natural ecosystems (Thiele-Bruhn et al., 2012; Delgado-Baquerizo et al., 2020; Wall et al., 2020, 2015). Soil biota can promote soil aggregation, thereby improving water infiltration owing to the effect of fungi and bacteria (Wall et al., 2015). The performance of these soil biodiversity functions is substantially influenced by the physicochemical properties of the soil, particularly pH and organic carbon content (Van Leeuwen et al., 2019), but also by the climate and management decision in agricultural systems.

Soil functions to support natural plant communities and crops are strongly linked to the metabolic activity of microorganisms and soil organic matter. Thus, the soil is a biochemical system highly regulated by the processes of decomposition of organic materials and inorganic transformations, carbon stock and greenhouse gas emissions (Bollag and Stotzky, 2000; Tabatabai, 1994). In the context of soil system functionality, determining enzyme activity is a tool used to verify whether the soil is fulfilling its functions to support natural plant communities and crops. In general, the enzymes linked to the carbon cycle (beta-glucosidase and dehydrogenase), nitrogen (urease), phosphorus (phosphatases) and sulfur (arylsulfatase) are more sensitive to changes that occur in the soil and have been proposed for use as quality indicators (Mendes et al., 2019).

Agricultural activities and management systems can alter the structure and richness of biological communities (Thiele-Bruhn et al., 2012). Soil management practices that alter organic matter content affect biological activity. Organic matter is a source of carbon for various organisms, such as soil microbiota (Delgado and Gomez, 2016). Conservation management techniques, such as no-till, crop residue maintenance, cover crops, crop rotation, integrated pest management, integrated soil fertility management (combination of organic and mineral fertilizers), and agroforestry practices increase soil biodiversity, thereby improving human, animal, and plant health owing to the suppression of disease-causing organisms and the supply of clean air, water, and food (Wall et al., 2015).

Transformation of potentially harmful elements and compounds

Soil acts as a geochemical sink for contaminants and a natural buffer controlling the transport of chemical elements and substances to the atmosphere, hydrosphere, and biota (Kabata-Pendias, 2011) and consequently plays a global ecological role. Therefore, processes of soil pollution can affect quickly and significantly the physical, chemical and biological properties of soil impacting the essential ecological functions of soil. According to Simon (2014), natural and human impacts can cause point-like or diffuse soil contamination and pollution. Industrial, agricultural, and urban activities release potentially harmful trace elements, which can cause soil and water contamination. In agricultural soils, Zheng et al. (2007) revealed that potentially toxic elements such as Cd, Cu, Hg, Pb, and Zn may influence plant nutrient uptake, and their concentrations in the tissues of food and fodder crops can affect the quality of food and drinking water with potential implications to human health.

The availability of potentially harmful elements and compounds to plants and microorganisms depends on the form they are present in the soil solution. This presence is governed by soil composition, soil reaction, oxidation-reduction conditions, and reaction kinetics, which in turn depends on soil attributes and their tendency to form insoluble precipitates and co-precipitates with other minerals, complexes with organic matter, and promote mineral absorption (Camargo et al., 2001).

Although the selectivity of each element for adsorption sites in soil particles differ considerably due to the chemical, physical, and mineralogical characteristics of the soils, the amount of metals retained is positively correlated with organic matter, CEC, specific surface, and clay and oxide content. pH is one of the most important soil solution parameters because it is positively correlated with the adsorption of metals (Ross, 1994).

Considered as a constituent of the soil matrix in the form of organic colloids, humus is made up of recalcitrant molecules from vegetable and microbial, combined through polymerization and resynthesis reactions, with phenolic compounds left over from lignin (Sutton and Sposito, 2005). The main effects of humus are the improvement in plant nutrition and in the physical and chemical properties of the soil, including the immobilization of potentially toxic elements and organic pollutants (Ameri and Tehranifar, 2013).

The remediation of potentially toxic elements also can be achieved through immobilization using different soil amendments, and details can be found in the chapter "Remediation of soils polluted with heavy metals & organic pollutants." However, soil properties such as pH, clay, sesquioxides, and organic matter content, and processes such as sorption/desorption and redox processes, are the key factors governing the effectiveness of amendments through the immobilization of potentially toxic elements in soils.

Conclusion

Soil functions can be affected by many biological, chemical, and physical factors, as well as the complex interactions among these factors. However, the ability of a soil to provide these functions depends on its properties. In this context, anthropogenic activities directly influence the sustainable productivity of soils, and conservation management systems are vital in maintaining soil health and quality and ensuring sustainable food production.

Abstract

Accumulation of the greenhouse gases carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O) in the Earth's atmosphere, resulting from human activities, is responsible for recent global heating and associated climate change. Natural soil emissions of CH₄ and N₂O are substantial, and increase after land conversion to agriculture, e.g., flooded rice fields release CH₄ and manures and synthetic nitrogen fertilizers promote the release of N₂O. Some mitigation of N₂O emission is achievable by improved nitrogen use efficiency. Replacement of fossil fuels by crop-based biofuels is controversial, because reduced CO₂ emissions can be largely offset by increases in those of N₂O.

Key points

- Emissions of the greenhouse gases methane (CH₄) and nitrous oxide (N₂O) from land contribute to global heating.
- The current concentration of CH₄ in the atmosphere is now over 2.5 times that in pre-industrial times.
- The global warming potential of CH₄ is c. 30 times that of CO₂ over a 100-year period, and >80 times greater over a 20-year period.
- Natural CH₄ sources include wetlands and termites; anthropogenic ones are principally rice fields and landfills.
- The main sinks for CH₄ are atmospheric processes.
- N₂O in the atmosphere has increased sharply over recent decades.
- Natural soils are the biggest emitter of N₂O, followed by agricultural soils.
- Increased use of N fertilizers and land conversion to agriculture are mainly responsible for increased N₂O emissions.
- N₂O emissions from crops grown for biofuels can offset much of the benefit from reduced fossil fuel use.

Introduction

Absorption of infrared radiation by natural concentrations of water vapor, carbon dioxide (CO₂), and trace gases in the atmosphere is responsible for the mean surface temperature of the Earth being approximately +15 °C rather than −18 °C. Additional heating caused by emissions of greenhouse gases (GHGs), resulting from human activities, has been superimposed on this very large, natural heating process. Although this extra heating is comparatively small (estimated to have currently raised the global mean temperature by 1.1 °C above the average for 1850–1900 (IPCC, 2021)), it is now accepted as being responsible for undesirable climate change, already manifested by extreme heatwaves and storms. Consequently, international efforts are being mobilized to limit emissions, and to restrict the maximum global temperature rise to 1.5 °C above pre-industrial levels, as embodied in the Paris Agreement signed in 2015 (UNFCCC, 2016).

The most important individual GHG is CO₂, but substantial contributions to global heating are made by trace gases, in particular methane (CH₄) and nitrous oxide (N₂O), both of which come in part from emissions from land, and which have much greater global warming potentials (GWP) than CO₂. The GWP of a GHG is a measure of its contribution to atmospheric global heating over a fixed period of time relative to that of CO₂, which is assigned a GWP of one. One kilogram of CH₄ has a GWP 28–36 times greater than 1 kg of CO₂ over a 100-year period, and 84–87 times greater over 20 years, while the GWP of 1 kg of N₂O is 265–298 times greater. A further contribution to global heating comes indirectly from tropospheric ozone, which is produced by light-catalyzed reactions involving nitric oxide (NO) and organic compounds emitted by vegetation. Nitric oxide is a natural product emitted from soils as well as from combustion processes. As well as being a source of CH₄ and N₂O, soils also act as a minor sink for CH₄ and N₂O already in the atmosphere (Smith, 2010; Reay et al., 2010).

Methane

Sources and sinks

The concentration of CH₄ in the atmosphere is now well over double that in the preindustrial era, up from approximately 0.7 ppm (0.7×10^{-6} mol mol⁻¹) to almost 1.9 ppm. The lifetime of CH₄ in the atmosphere is quite short, c.10 years; the main removal pathway or sink is through oxidation by UV-created hydroxyl radicals (OH) in the atmosphere, while 5% is oxidized by soil microorganisms. No single source is responsible for the atmospheric increase, but soils (including soil fauna) contribute approximately 50% of total emissions (Table 1). Global emissions of CH₄ are estimated at 559 (range 540–568) Tg CH₄ year⁻¹ for the 2003 to 2012 decade (Saunois et al., 2016).

Soil sources

Methane is formed in soils by a process called methanogenesis, which is the microbial breakdown of organic compounds in strictly anaerobic conditions (Conrad, 1996). A very low redox potential is required for this process, and CH₄ production does not begin until reduction of molecular oxygen, nitrate, iron(III), manganese(IV) and sulfate (all of which maintain the potential at higher levels) is complete. Such low-redox conditions are predominantly found in soils where prolonged waterlogging is a normal feature, e.g., natural wetlands and flooded rice fields, and beneath the soil cover of closed landfills, as well as in the sediments at the bottoms of lakes. The original identification of CH₄ as a main component of the gas released as bubbles from natural marshes was made by Alessandro Volta in Italy in 1776. The gas is still known by the name ‘marsh gas’ given to it at that time.

The organic compounds that provide the carbon for CH₄ formation in marshes, bogs, and flooded soils are released from living roots or come from the microbial degradation of plant remains in a bogland plant community, or rice straw ploughed into the soil of a paddy field prior to the establishment of the next crop. The final step in the decomposition is performed by methanogens, i.e., methane-producing archaea (Stams and Plugge, 2010), giving rise to CH₄ and CO₂ in equimolar quantities, according to the equation:

The CH₄ formed in this way can migrate to the surface and be emitted into the atmosphere by one of three different pathways (Fig. 1). Diffusion can take place in solution from the point of formation in an anaerobic layer, upward to water layers containing

Table 1 Estimated soil sources of CH₄ emissions and soil and atmospheric sinks (taken from IPCC, 2013).

oxygen, where much of the CH₄ is oxidized and only a fraction outgasses to the atmosphere. When sufficient gas is produced to exceed the solubility product, bubbles form in the water layer, and force their way to the surface—the process of ebullition that prompted Volta's original investigation. The speed of this process prevents any significant oxidation. The third route is via the internal structures of vascular plants. Many species that are adapted to life in flooded environments contain continuous air spaces that connect the leaves and stems to the roots. These structures, known as aerenchyma (Fig. 2), have evolved to transport oxygen needed for cell division to the root meristems, but serve equally well as channels for the transport of CH₄ from the root environment to the atmosphere.

In natural wetlands, CH₄ emissions vary with temperature, depth to the water table and the type and amount of vegetation present (Turetsky et al., 2014). Fig. 3 shows the steep increase in CH₄ emissions from boreal bogs and fens with increasing temperature and decreasing depth to the water table. Although many investigations have been made into emissions from temperate and boreal wetlands, the degree of uncertainty about total emissions, including the additional methane emitted as Arctic permafrost thaws, is still large. The uncertainty is greater still over emissions from tropical wetlands, because fewer studies have been made, and there is thought to be a much bigger contribution from seasonally flooded environments (e.g., Ringeval et al., 2014). Tropical river basins such as those of the Amazon and Paraná in South America, and the Congo in Africa, are prime examples of such seasonal flood plains, in which there is typically a rapid development of lush vegetation with the advent of the water, followed by decomposition under the floodwater and consequent CH₄ production. However, the flooded areas vary considerably in extent and mean flooding depth from year to year.

In the absence of adequate experimental data, mathematical modeling of regional emissions has made an important contribution to the assessment of wetland emissions. Observed seasonal variations in the concentrations of CH₄ in the atmosphere at different latitudes can now be simulated reasonably well by such models. Generally these models predict that more than 50% of global wetland emissions are of tropical origin.

Rice cultivation is also a major CH₄ source. Estimates compiled by the Intergovernmental Panel on Climate Change (2013) put the annual global emission from rice fields at approximately 36 Tg CH₄ year⁻¹ (Table 1). The area devoted to the rice crop has expanded considerably in recent decades, and global production is predicted to rise still further in the future, to meet the needs of rising populations. This trend has undoubtedly contributed to the increase in overall CH₄ emissions observed in the last few decades. An international program of research has been carried out to investigate the principal factors that determine the magnitude of emissions from rice. This has shown that soil type, crop fertilization, the amount of straw or organic manure incorporated into the soil before planting, and the continuity of the flooding regime, as well as climate, are all important.

In warm climates, CH₄ production also occurs in some aerobic soils, as well as in wetlands, but here the source is the microorganisms that live symbiotically in the guts of some species of burrowing and mound-forming termites, and not the free-living soil microflora (Bignell, 2010).

Soil sink for methane

The phenomenon of CH₄ oxidation by soil bacteria is general in aerated soils (Fig. 1). In well-drained and therefore well-aerated soils, in the absence of termites, any CH₄ present is largely that which has diffused in from the atmosphere, where the concentration

Fig. 2 Scanning electron micrographs of transverse sections through the vegetative organs of some vascular wetland plants, showing the aerenchyma through which oxygen and methane can readily diffuse: (A) *Eriophorum angustifolium* leaf; (B) *Carex echinata* root (at a depth of 100–110 mm); and (C) *Molinia caerulea* root (at a depth of c. 150 mm). Reproduced with permission from Thomas KL, et al. (1996) Role of wetland plants in the diurnal control of CH₄ and CO₂ fluxes in peat. *Soil Biology and Biochemistry* 28: 17–23.

is approximately 1.9 ppm. This CH₄ is oxidized to CO₂ by methanotrophic bacteria that are adapted to living on this very low concentration of substrate. The overall global sink for atmospheric CH₄ in soils is estimated at approximately 28 Tg year⁻¹; this is about 4% of total annual emissions from all sources (Table 1).

Soil bulk density and water content, and their consequent effects on gas movement and penetration in the soil profile, have a major impact on the rate of oxidation of atmospheric CH₄ in soils. Rates are highest in coarse-textured forest soils with well-developed soil structure and a permeable surface organic layer. Increasing soil acidity reduces oxidation; part of the explanation is that in acid conditions plant litter decomposes less readily and accumulates at the soil surface. This litter, particularly the leaves of broadleaved deciduous trees, acts as a diffusion barrier to gas exchange between the soil and the atmosphere. The effect of soil temperature on oxidation rate is small, and this is attributed to limitations imposed by the supply of available CH₄ substrate, due to the combined effects of diffusion resistance and low atmospheric concentration.

In addition to the oxidation of atmospheric CH₄ in soils, there is also oxidation of a fraction (perhaps 20–30%) of the CH₄ produced in soils before it escapes to the atmosphere. The methanotrophic bacteria responsible live in, e.g., the thin, aerated

Fig. 3 Interactions between soil temperature and water table govern methane flux. Surface plots of relationships between observed instantaneous methane flux, soil temperature and water table position across (A) pristine boreal bogs, (B) pristine boreal poor fens, (C) pristine boreal rich fens, (D) drained bogs, (E) drained rich fens. sheath of soil that exists around the roots of vascular plants growing in flooded conditions, and in intercellular spaces within plant root systems. They also occur in aerobic hummocks on the tops of bogs, as well as in aerated cover soils above anaerobic refuse layers in landfills. In such environments, average CH₄ concentrations may be very much higher than those resulting from gas diffusion from the atmosphere, and different mixed populations of bacteria, capable of assimilating CH₄ at a faster rate than those adapted to atmospheric concentrations, become established.

As a result of deleterious effects of soil disturbance and additions of nitrogenous fertilizers on methanotrophic organisms, conversion of natural soils to agricultural use reduces CH₄ oxidation rates by approximately two-thirds. Recovery of oxidation rate from land-use change or fertilization is slow; it may take 100 years or more to return to pre-disturbance rates. The reasons for this unusually long period of adjustment may be related to slow-changing soil properties such as soil organic matter composition or microbial community structure (Suwanwaree and Robertson, 2005).

Efforts to reduce methane emissions

Methane is a good target for mitigation because it has a short atmospheric lifetime (c. 10 years) and the benefits of reduced emissions would be apparent over a relatively short time (Cloy et al., 2012). Attempts are being made to reduce net CH₄ emissions from two major sources: sanitary landfills and flooded rice fields. Paradoxically, the creation of closed landfills for municipal wastes to prevent other problems associated with unconfined piles of refuse has brought about a major increase in the amounts of CH₄ produced. This is because compacted clay layers in the soil caps exclude atmospheric oxygen, thus allowing the landfills to become anaerobic. However, the general recognition of the undesirable contribution of these sites to global heating has led to the development of effective engineering solutions for application to large modern landfills. These range from the venting and burning on-site of the CH₄ (converting it to CO₂, which on a 20-year timescale is less than one-eightieth as potent a GHG), to its collection and use in energy production, thus gaining an additional benefit through reducing the use of fossil fuel for that purpose. In both the USA and the EU, these measures have brought about a reduction in landfill CH₄ emissions (though in developing countries increased landfilling will likely result in increased emissions) (Bogner and Spokas, 2010). For many older and smaller landfills, however, there is little scope for economic installation of CH₄ collection and recovery equipment. For such environments the more effective option is the promotion of CH₄ oxidation in the cover soil. The oxidation is optimal in cover soils of intermediate textures and moderate water contents, which permit a reasonable rate of diffusion through the soil matrix and thus allow oxidation to take place, but avoid the development of cracks through which gas may be vented rapidly to the surface.

There is potential for reducing substantially the average CH₄ emissions from traditionally flooded paddy fields. In recent years there has been a move away from permanently flooded production systems, to more productive cultivation systems involving periodic flooding or dryland production (Conen et al., 2010). Water management that involves multiple cycles of flooding and draining of the soil has been shown to reduce CH₄ emissions by 40%. Reduced inputs of crop residues prior to flooding can also reduce emissions. Such changes to traditional methods can be made without detriment to crop yields and sometimes bring with them other agronomic or cost benefits—at worst they can usually be introduced without increasing the cost or difficulty of farming operations. However, persuading farmers to use such new methods takes much advisory effort, and the rate of adoption varies greatly among different societies, unless incentives are introduced.

Nitrous oxide

Soil sources

The natural cycle of N₂O in the environment involves microbial and chemical production in soils and waters, and ultimate decomposition in the stratosphere. Approximately 65% of all atmospheric emissions of N₂O are from soils. Ice-core data show that the concentration of N₂O in the atmosphere in the preindustrial era was approximately 275 ppb ($275 \times 10^{-9} \text{ mol mol}^{-1}$), but this had increased to about 331 ppb in 2018 (Tian et al., 2020). This increase in atmospheric N₂O is attributed to increased anthropogenic emissions, through increased production and use of N fertilizers, tropical land conversion from forest to agriculture, increased biomass burning, etc. Recent modeling also suggests an increased emission from natural soils, as a result of global N deposition and climate change (Tian et al., 2020). The extra emissions have not been accompanied by any corresponding increases in the sinks for N₂O. The dominant sink is the reaction with ozone in the stratosphere to produce NO, which was the process that first generated the environmental concern about N₂O because of its potential for increasing UV radiation at the Earth's surface (Table 2). In addition, a very small soil sink (uptake of N₂O in soil) has been suggested, and attributed to a reduction of overlying atmospheric N₂O to N₂ during denitrification, the only proven terrestrial biological N₂O sink. However, there is no direct supporting experimental evidence (Smith, 2010).

Nitrous oxide production in soil results predominantly from a range of microbial processes: nitrification, denitrification, nitrifier denitrification and nitrate ammonification (Conrad, 1996). Their pathways are shown in Fig. 4; those generally regarded as most important for N₂O production are autotrophic nitrification, involving ammonia-oxidizing *Nitrosomonas* and *Nitrosospira* bacteria, and heterotrophic denitrification, brought about by a wide range of bacteria, together with some archaea and fungi (Baggs and Phillipot, 2010). Non-biological formation of N₂O, chemodenitrification, can also occur in soil, either through the reaction of

Table 2 Estimated soil sources of N₂O emissions and stratospheric sink (Tg N₂O-N year⁻¹) (taken from IPCC, 2013).

Sources	Global annual emission	Range
<i>Natural</i>		
Soils under natural vegetation	6.6	3.3–9.0
<i>Anthropogenic</i>		
Agriculture (direct emissions from cultivated/fertilized soils and animal production)	4.1	1.7–4.8
Atmospheric N deposition on land	0.4	0.3–0.9
Total from soils/agriculture	11.1	5.3–14.7
Total from all sources	17.9	
Observed atmospheric increase	3.6	3.5–3.8
Stratospheric sink	14.3	4.3–27.2

**Fig. 4** Soil microbial processes leading to N₂O production. In: Smith KA (2017) Changing views of nitrous oxide emissions from agricultural soils: Key controlling processes and assessment at different spatial scales. *European Journal of Soil Science* 68: 137–155.

nitrite with the constituents of organic matter, or by the reduction of nitrate by iron (II). The available evidence suggests that the former pathway constitutes a very small source compared with the microbial ones, but the latter could be more significant.

There are strong relationships between the state of aeration of soils and the balance between nitrification and denitrification as the main sources of N₂O emissions. As soil wetness increases, the availability of oxygen from the atmosphere decreases, and nitrification is inhibited. Conversely, denitrification, which is very variable in time and space, is generally promoted. Both processes can occur in the soil in close proximity to each other (Conrad, 1996).

Natural soil N₂O emissions per unit area in the tropics are about 50% higher than the global average, because many lowland, highly weathered tropical soils have excess nitrogen relative to phosphorus (Davidson et al., 2007; Tian et al., 2020). These tropical emissions have been estimated to total 3 Tg N₂O-N year⁻¹ while those from temperate forests, temperate grasslands and tropical dry savannas are each thought to contribute in the order of 1 Tg year⁻¹ (Kroeze et al., 1999). A global total of 6.6 Tg N₂O-N year⁻¹ from all natural soils has been estimated by the IPCC (Table 2). The uncertainty associated with this estimate is in the order of ±50%. Global long-term average soil N₂O emissions from croplands were estimated at 3.6 Tg N₂O-N year⁻¹ (ranging from 2.96–4.35 Tg N₂O-N year⁻¹) from 1996 to 2013 (Yang et al., 2021).

Nitrous oxide emissions from agricultural soils

Reactive N compounds are introduced into the natural terrestrial environment primarily by biological nitrogen fixation (BNF) in forests and grasslands, particularly in the tropics. The N input by this pathway in the pre-industrial era (up to 1860) was estimated by Galloway et al. (2004) at 120 Tg N year⁻¹ in 1860, but human activity has now roughly doubled the N supply to the biosphere

Fig. 5 Sources and pathways of reactive nitrogen compounds that result in N_2O emissions from soils and waters. From de Klein C, et al. (2006) N_2O emissions from managed soils and CO_2 emissions from lime and urea application. In Eggleston HS, Buendia L, Miwa K, Ngara Y, and Tanabe K. (eds.), *2006 IPCC Guidelines for National Greenhouse Gas Inventories*, Vol. 4, Chapter 11, Hayama, Japan: IGES.

through synthetic N fertilizers—the worldwide demand for 2020 was 109 Tg N (FAO, 2019)—together with a smaller amount through BNF by leguminous crops, and also inadvertently as NO_x from fossil fuel combustion. Consequently, human-induced emissions of N_2O are dominated by N additions to land, and have increased by 30% over the past four decades to 7.3 (4.2–11.4) Tg N year⁻¹ (Tian et al., 2020).

Fig. 5 shows schematically the sources and pathways of reactive N compounds that result in N_2O emissions from soil and water. As the Figure shows, agricultural soil emissions are not only from land receiving mineral N fertilizers, but also from land receiving animal manures, either applied by farmers or directly deposited as the excreta of grazing livestock. The steady increase in the size of livestock populations over time has contributed substantially to the present-day emissions level. Increases in food production are regarded as essential to meet the needs of a growing population, over the next few decades, and are likely to require increased use of N, both for crops intended for direct human consumption, and for animal feed crops; this trend may be expected to increase overall N_2O emissions.

Soil emissions determinants

Fluctuations in soil physical conditions and mineral N content in agricultural soil cause large variations in N_2O emissions. Consequently, rainfall events and applications of fertilizer that cause step-changes in soil wetness and mineral N content, respectively, are often associated with emission pulses, as shown in Fig. 6. The largest fluxes generally occur when soil water-filled pore space (WFPS) values are high, indicating that denitrification is the major process responsible.

On grazed land, the deposition of excreted N is spatially very variable. A small patch of soil surface may receive N as urine at a rate equivalent to some hundreds of kilograms per hectare, whereas land between patches receives none. Also, treading of the soil surface in wet conditions by animal hooves can create localized compacted zones in which water collects and the soil becomes

Fig. 6 Nitrous oxide emissions from grassland at 5 UK sites, fertilized with different forms of nitrogen fertilizer: ammonium nitrate (or calcium ammonium nitrate) and urea, with and without the nitrification inhibitor dicyandiamide. The figure shows variation in daily precipitation and soil water-filled pore space (WFPS) throughout the experimental period, and mean N_2O emissions from all N treatments. Continuous arrows show dates of main N fertilizer applications, and dashed arrows show dates of extra fertilizer additions in split application treatments. From Cardenas LM, et al. (2019) Nitrogen use efficiency and nitrous oxide emissions from five UK fertilised grasslands. *Science of the Total Environment* 661: 696–710.

anaerobic. Such factors lead to the occurrence of ‘hotspots’ of microbial activity and N_2O emission; overall the average emission rate from grazed grassland may be two to three times that from N-fertilized grass grown as a crop to be cut for winter feed. In Western Europe at least, the emissions from cut grassland are, in turn, substantially higher than emission rates from arable land cropped with wheat and barley. This is attributable to a combination of soil physical conditions and the timing of N applications. However, the emissions are very variable between sites and between successive seasons, and for any crop type several years’ data are required to obtain a robust estimate of annual N_2O flux (Dobbie and Smith, 2003).

Potential for reducing nitrous oxide emissions

With food security an issue (see Chapter on Soil and Human Health), reducing production is not a viable option. Instead, ‘sustainable intensification’ practices that aim to produce ‘more with less,’ e.g., improving N-use efficiency (NUE), offer the best opportunity of reducing emissions from agricultural soils. In general, the procedures recognized as helping in this direction include:

- Avoiding excessive inputs of N and optimizing plant N through soil/plant testing to determine fertilizer N needs;
- Minimizing fallow periods to limit mineral N accumulation;
- Improving the timing of and or splitting of N applications;
- Using ‘controlled release’ N fertilizers, which make the N available for crop uptake over an extended period;
- Adding urease inhibitors and nitrification inhibitors to urea and ammonium fertilizers;
- Matching the fertilizer type to the soil water regime, e.g., by using an ammonium form in circumstances where wet soil conditions are likely to cause excessive denitrification losses from nitrate forms.

The widespread adoption of these measures could reduce total emissions by 20–25%.

Emission factors

National emissions of GHGs are generally reported using Intergovernmental Panel on Climate Change (IPCC) methodology. For each significant source, an emission factor (EF) is multiplied by the size of the source: the so-called ‘activity data’. Thus, e.g., direct soil emissions of N_2O are calculated by multiplying the fraction of the applied N that is emitted as N_2O , by the total mass of N applied. ‘Default values’ for EF are used where there are no measurement data for the country involved that meet the necessary quality criteria: 1% for direct soil emissions from applied fertilizer and manure N, 2% for N deposited by grazing livestock, 0.3–0.4% for indirect emissions following N loss by leaching, run-off or volatilization (IPCC, 2006; Cloy et al., 2012). Using an ensemble of process-based models, Tian et al. (2020) estimated a global agricultural soil EF of 1.8% (1.3–2.3%), which is considerably larger than the IPCC Tier 1 default for direct emission of 1%, and suggest that this is caused by a strong interactive effect between N additions and other global environmental changes. They calculated that anthropogenic N_2O emissions increased from 5.6 (3.6–8.7) Tg N year^{-1} in the 1980s to 7.3 (4.2–11.4) Tg N year^{-1} in 2007–16, at a rate of 0.6 ± 0.2 Tg N year^{-1} per decade ($P < 0.05$). Up to 87% of this increase (71% directly and 16% indirectly) resulted from N additions to soils. The bottom-up land emissions estimate during 1998–2016 was on average 1.8 Tg N year^{-1} higher than the top-down estimate, but showed a slightly slower rate of increase of 0.8 ± 0.2 Tg N year^{-1} per decade (95% confidence interval; $P < 0.05$) compared with 1.1 ± 0.6 Tg N year^{-1} per decade ($P < 0.05$) from the top-down approach.

An alternative ‘top-down’ approach took the reactive N (Nr) entering agricultural systems as the source of all agriculture-related N_2O emissions. On the basis of the observed rate of increase in the atmospheric concentration of N_2O , this gave a global EF of 3–5% for the year 2000 (Crutzen et al., 2008). Furthermore, including two other Nr sources—the N mineralized as a result of land-use change and N deposited as NO_x —and applying an overall EF of 4% shows a very close match with the observed upward trend in the atmospheric concentration of N_2O over the 140 years between 1860 and 2000 (Smith et al., 2012), as shown in Fig. 7.

Crop-based biofuels and nitrous oxide emission factors

The agricultural sector is faced with a growing demand for food and the consequent need to increase food supply. However, the surge in the production of crops for biofuels has also increased the pressure on land resources. Life cycle analysis (LCA) models generally indicate that crop-based biofuels generate GHG savings compared with fossil fuels. However, applying a 4% global EF for N_2O , and a global mean value for nitrogen use efficiency (NUE) of 40–50% can cancel out these GHG savings (Crutzen et al., 2008). Use of these global figures is inevitably controversial. There are circumstances in which sophisticated farm management results in a much higher NUE than the global average, which would correspondingly diminish the N_2O emission per unit of crop-based biofuel. However, given the absence of any controls on production methods for biofuel feedstocks, there is a case for the precautionary use of the global mean values, when assessing the potential environmental benefits from switching from fossil fuels to biofuels. Overall, it appears that deriving biofuels from biomass, from waste feedstocks, or high-yielding bioenergy crops with low N demand grown on currently unproductive land, rather than from N-fertilized crops, would be the best option for GHG mitigation (Smith and Searchinger, 2012).

Fig. 7 Comparison between observed increase in atmospheric concentration of N_2O over the period 1860–2000 (black circles) and calculated increase based on a 4% emission factor (EF) for new reactive N, including N from synthetic fertilizers, from additional N from biological N fixation (BNF) above the rate of fixation in 1860, from NO_x -N, and from N mineralized from soil organic matter as a result of land-use change to agriculture (red triangles). Bottom curve (inverted triangles) includes all these sources except mineralized N. Blue and green squares indicate the increase for EFs of 3 and 5%, respectively. Based on data in Davidson EA (2009) The contribution of manure and fertilizer nitrogen to atmospheric nitrous oxide since 1860. *Nature Geosciences* 2: 659–662; and Butterbach-Bahl K, et al. (2011) Nitrogen as a threat to the European greenhouse balance. In Sutton MA, et al. (eds.) *The European Nitrogen Assessment*, pp. 434–462. Cambridge, UK: Cambridge University Press. Adapted from Smith KA, et al. (2012) The role of N_2O derived from biofuels, and from agriculture in general, in Earth's climate. *Philosophical Transactions of the Royal Society, Series B* 367: 1169–1174.

Summary

Emissions of the greenhouse gases carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) are responsible for global heating, resulting from human activities. Methane and N_2O are more potent greenhouse gases than CO_2 , and their emissions from land are significant. Natural CH_4 sources include wetlands and termites; anthropogenic ones are principally rice fields and landfills. The main sinks for CH_4 are atmospheric processes, with only a small soil sink. Natural soils are the biggest terrestrial emitter of N_2O , followed by agricultural soils. Increased use of N fertilizers, land conversion to agriculture, and climate change, are mainly responsible for increased N_2O emissions over recent decades. The N_2O from crops grown for biofuels can offset much of the benefit from reduced fossil fuel use.

Abstract

Globally, soils are being degraded at an unprecedented rate. This chapter provides an overview on the extent of soil degradation and its main anthropogenic controlling factors. Most controlling factors are related to land mismanagement or overexploitation to satisfy the increasing demands of the growing global population. Positive feedback loops between climate change, land-use changes and socio-political pressures exacerbate soil degradation. This chapter also briefly introduces the chapters that focus on soil quality and monitoring, physical and chemical soil degradation processes, for example, erosion, pollution and salination, and biological soil degradation processes. Novel remediation approaches for contaminated soils are summarized, which aim to restore degraded lands to safe and beneficial reuse.

Key points

- Soil degradation is a major global problem
- It is caused by anthropogenic and natural factors
- Physical soil degradation processes include wind and water erosion, and the loss of soil structure
- Chemical soil degradation processes are mostly related to anthropogenic activities and include salination, overfertilization, and pollution with trace elements, microplastics and organic chemicals
- Major biological soil degradation processes are losses of soil organic matter and biodiversity. The functioning of soil biodiversity and community composition are still poorly understood. The relevance of biological soil degradation, however, is more and more recognized

Introduction

Soils are degrading worldwide at an unprecedented rate mainly resulting from unsustainable human activities (FAO and ITPS, 2015). This chapter provides an overview of chapters in the Encyclopedia that deal with soil quality and monitoring, soil degradation, and the remediation of contaminated soils.

Soil, the skin of the earth, plays a fundamental role for humanity. In concepts integrating the economic worldview with ecological principles, soil is considered as natural capital stock. Soils deliver many essential ecosystem services such as provisioning services, regulating and supporting services (Costanza et al., 1997). Soils provide humans with 98.8% of our food (Kopittke et al., 2019) and are essential for achieving many of the Sustainable Development Goals (SDGs) including zero hunger, clean water and flood regulation (Keesstra et al., 2016). The total value of ecosystem services provided by soils is estimated at US\$ 11.4 trillion (McBratney et al., 2017). Soil is considered a non-renewable resource in the human lifetime because its formation takes centuries to millennia. It is a living ecosystem, and its functioning including, for example, nutrient cycling, water infiltration and retention, and contaminant filtering, is affected by natural forces and anthropogenic activities.

Soil functioning and the delivery of ecosystem services depend on soil quality. There is a growing body of literature on defining soil quality, identifying its key indicators, measuring changes in soil quality, and defining soil degradation (Gomiero, 2016; Bünemann et al., 2018). Constantini and Piori (2023) discuss the importance of informed selection and analysis of soil quality indicators and highlight that interpretation and use of the data require close cooperation of professionals with different and specific expertise. Definitions and common determinators are needed for developing soil protection policies. Monitoring of soil quality

and policy implementation remain challenging because changes in soil properties are often only apparent on decadal timescales and soil monitoring is a long-term commitment (Marchant and Saby, 2023). The authors of this chapter highlight essential features such that soil monitoring networks need to be cost-effective and robust to changing land uses, technological advances, and evolving soil quality priorities.

To date, however, the geographical distribution and total areas affected by soil degradation are still only roughly known. Estimates of global soil degradation range between less than 1 Gha to more than 6 Gha (Gibbs and Salmon, 2015; Fig. 1) reflecting the challenges of defining 'soil degradation', unreliable quantitative and qualitative data sources, differences in models and their assumptions, and missing information in general. By 2050, it is estimated that soil degradation will affect 90% of the soils globally (FAO and ITPS, 2015). Once a soil is degraded, its restoration in general is not straightforward. It can be costly and take a long time depending on the type and degree of the degradation, inherent land and soil properties, land use and climate. Better understanding of the drivers, threats and consequences of soil degradation, plus assessments of the costs of non-action, will support the development of a global soil protection policy and effective soil protection strategies.

Factors controlling soil degradation

Global population growth and changing diets in many parts of the world have increased the demand for food, feed and fuel, and have necessitated agricultural intensification to ensure food security for the growing population (Kraamwinkel et al., 2021). Significant yield increases achieved during the 'Green Revolution' in the middle of the last century were possible through massive increases in agricultural resource inputs, including water, energy, pesticides and fertilizers, and other technological advances such as the double-cropping and development of new cultivars. One of the harmful unintended environmental consequences of the 'Green Revolution' was widespread soil degradation (John and Babu, 2021).

Land-use change has threatened soil for millennia. Deforestation is the first step to convert natural vegetation into agricultural land and it often induces soil organic carbon loss and soil erosion processes, particularly in the tropics (Don et al., 2011; Pimentel

Fig. 1 Maps of land areas (percent of cell area; 20 k grid) affected by degradation; each panel represents a different method of modelling method described by Gibbs and Salmon (2015). Taken from Gibbs HK and Salmon JM (2015) Mapping the world's degraded lands. *Applied Geography* 57: 12–21.

and Burgess, 2013). Land-use change to extensive grasslands for cattle has reduced soil biodiversity and often leads to soil compaction (Centeri, 2022). Irrigation with poor quality water has increased soil salinity in many subtropical regions (Topcu, 2023; Qadir and Scott, 2023). Implementation of high value cash crops such as avocado (*Persea americana* Mill.), oil palm (*Elaeis guineensis* Jacq.), etc. might reverse rates of erosion because these crops keep the soil covered. However, they introduce agrochemicals in large amounts, which have been shown to reduce soil biological activity and can pollute soil and groundwater in the mid to long term (Meena et al., 2020). Recently, urbanization is sealing fertile land in some regions of Europe and North America and is now recognized as the most important soil degradation factor in populated areas (Scalenghe and Marsan, 2009).

Global population expansion further fosters the production of large volumes of waste, and augments pressure from other economic sectors such as industry, transport, and tourism on soil. The demands of agriculture and other economic sectors on soil are often competing and conflicting and contribute to soil degradation (Fig. 2).

Climate change is presenting a further threat to soil. Temperature increases, increased frequency of extreme rainfall events, and prolonged droughts are affecting biomass production and vegetation cover of natural ecosystems and its soils, and these effects are also closely interrelated with human land-use decisions. Resulting land-use changes go hand in hand with changing soil management practices that can further enhance soil degradation. Positive feedback loops between climate change, land-use changes and social and political pressures can exacerbate soil degradation.

Types of soil degradation

Lal (2015) classified soil degradation into physical, chemical, biological, and ecological degradation (Fig. 3). In the following chapters, a selection of types of physical and chemical soil degradation and their controlling factors are outlined. While types of biological soil degradation are not explicitly included in this section, soil organic matter loss is discussed jointly with the loss of soil structure in the chapter by Gregory (2023), and we provide a brief overview on biological degradation here.

Physical soil degradation

Physical soil degradation can, for example, occur as soil erosion, loss of soil structure, desertification, sealing and crust formation (Fig. 3). The chapters by Rickson (2023) and Tartako (2023) describe soil erosion processes, which are defined as the detachment and transport of the usually fertile topsoil material by water or wind. Climate change, land-use change, removal of vegetation and soil disturbance by human activities can accelerate topsoil loss, often exceeding the rates of soil renewal. As soil is lost to erosion, vital ecosystem services delivered by soil are also lost, and eventually the remaining soil is rendered infertile. Rickson (2023) presents the fundamental principles of water erosion, both measurement and monitoring approaches at different scales, and discusses modelling methodology as mitigation strategies. Tartako (2023) highlights that wind erosion, which occurs when strong winds impact loose, dry, or bare soils, is a global concern with significant on-site and off-site effects. The author uses cropland as an example to explore causes, effects, and controls of wind erosion. The general principles, however, are applicable to all landscapes.

Fig. 2 Drivers, threats and consequences of soil degradation (Kraamwinkel et al., 2021).

Fig. 3 Types of soil degradation (Lal, 2015).

A loss of soil structure, which is closely related to the loss of soil organic matter, is another physical process of soil degradation. Soil structure and organic matter are two dynamic soil properties that facilitate most soil processes at all spatial and temporal scales. The largest component of organic matter is carbon, and hence degradation of soil structure can have implications for the global carbon cycle and climate change. Gregory (2023) summarizes the symbiotic degradation of soil structure and organic matter including the main causes and effects of degradation on soil structure and soil organic matter, and the subsequent effects on soil functions.

Chemical soil degradation

Soil degradation can also occur as a result of chemical processes. Acidification, salination, elemental imbalances, decline in cation exchange capacity and soil contamination are examples of chemical soil degradation (Lal, 2015).

Agricultural productivity has been increased through increasing resource inputs. For example, during the last 70 years mineral fertilizer applications fundamentally changed soil and crop management. Singh and Sapkota (2023) outline how fertilizers increase the availability of essential plant nutrients in soils and enhance the natural productivity of soils. However, excessive fertilizer applications may also degrade soils by altering their natural functioning, which can lead to major and sometimes irrevocable changes in soil characteristics, e.g., nitrogen fertilizer may cause soil acidification, and soils may be contaminated with trace elements contained in rock phosphates, or in fungicides such as those used preventively in vineyards or other permanent high value cash crops.

Similarly, Topcu (2023) describes how irrigation of agricultural land has contributed to yield increases. Although approximately 25% only of the world's arable land is under irrigation, it accounts for more than 60% of the cereal production worldwide and 50% of the sales value of all crops harvested come from irrigated agriculture (Angelakis et al., 2020). Freshwater resources, however, are scarce and water scarcity is a major global issue (Mancosu et al., 2015). Current irrigation practices affect the availability and quality of soil and water resources. Agriculture is the largest water user and accounts for almost 80% of the global water use (Famiglietti, 2014). Topcu (2023) outlines options for improving the environmental performance of irrigation while increasing water

productivity in irrigated agriculture. Achieving these complementary goals is important for the long-term sustainability of irrigated agriculture.

The use of treated wastewater for irrigation offers a significant opportunity to increase productivity, particularly in water scarce areas. Most non-potable options for the use of wastewater require quality lower than that of drinking water, and wastewater can be treated for irrigation. Qadir and Scott (2023) provide an overview of wastewater irrigation and assess the trade-offs between the positive aspects of wastewater irrigation (year-round water supply, savings on fertilizer, less cost for pumping, increase in soil organic matter, and greater income from high-value crops) in relation to the negative risks (unbalanced plant nutrient application, increased soil salinity, metal ion pollution, and exposure to emerging contaminants and pathogens). Balancing these trade-offs requires positive outcomes to be ensured while minimizing risks through wastewater treatment and use compatible with its quality. A serious problem in developing countries is the use of large volumes of untreated or inadequately treated wastewater in agriculture, where governments do not spend resources to build wastewater treatment plants (Jones et al., 2021).

It is estimated that, worldwide, more than 50% of croplands will be salinized by 2050 (Jamil et al., 2011). Major causes of anthropogenic soil salination in arable lands are irrigation with saline water and improper soil drainage. Nachson and Levy (2023) differentiate between anthropogenic and natural salination processes. The authors discuss the effects of soil salination and practices that can be employed to overcome this challenge, including soil reclamation.

The expansion of irrigated areas is unsustainable, however, without proper drainage and funding for the appropriate implementation of technical and socioeconomic aspects. Drainage, the topic addressed by Strock (2023), is defined as the natural or artificial removal of water from the land either through surface drainage, subsurface drainage or a combination of both. The practice of land drainage may be beneficial if poorly drained conditions result from shallow groundwater or soils have low permeability. In agricultural settings, many soils require artificial drainage to improve field trafficability for field operations and to protect growing crops from excess soil water. Drainage has direct and indirect effects on the provision of ecosystem services including impacts on soil organic carbon stocks, organisms living in the soil, nutrient cycling, water retention, greenhouse gas emissions, and nutrient losses to surface and groundwater.

Soil contamination is defined as the presence of substances in soil, at concentrations higher than would either occur naturally, or through sustainable soil management practices. Soil contaminants include trace elements, radionuclides, pesticides, plant nutrients, fuels, solvents, crude oil, other organic substances, pharmaceuticals, and personal care products. Sources of contamination can be divided into point and nonpoint (diffuse) and can occur through applications of agricultural inputs, mining activities, combustion of fossil fuels, spills, wet and dry deposition, land application of by-products, and flooding (FAO and ITPS, 2015). In the Encyclopedia, three soil pollutants are discussed that result in soil degradation, namely trace elements, organic chemicals and microplastics.

Soils are the major sink for trace elements released from agricultural (e.g., mineral and organic fertilizers, pesticides) and industrial activities (e.g., mining, disposal of wastes). While trace elements do not undergo microbial or chemical degradation their chemical speciation can change, which affects their bioavailability, fate, and subsequent risk in soils. Wang et al. (2023) emphasize that trace elements of anthropogenic origin are generally present in more mobile and bioavailable fractions.

Kookana and Navarro (2023) highlight the problem of the long persistence time of some organic pollutants in the soil environment; the persistent organic pollutants (POPs). Their chapter provides an overview of how the chemical properties and fundamental processes of conventional POPs (e.g., polyaromatic hydrocarbons, polybrominated diphenyl ethers) as well as new POPs (e.g., *per*- and poly-fluoro alkyl substances - PFAS) control their fate and behavior in the soil environment and determine their potential impact on biota.

The chapter by Huerta Lwanga and Beriot (2023) introduces the issue of plastic pollution in agricultural soil. Plastic pollution occurs when plastic materials are fragmented into macroplastics (>5 mm) and microplastics (<5 mm), or when they are applied inadvertently with amendments such as composts or sewage sludge. The impacts of plastic particles on soil physical properties, plants, invertebrates and vertebrates, the biotic and abiotic transport of micro and nanoplastics through soils, and their transfer into the food chain are discussed.

Another aspect of the global population expansion is the generation of large volumes of diverse waste, which can cause soil degradation if not properly managed. As a subset of global waste, municipal solid waste includes household, business, institutional, and construction waste that may be processed, composted, recycled, and or disposed of at managed sites. Serre and McCarthy (2023) describe various municipal waste management strategies in Western societies, including recycling, composting, energy recovery, treatment and disposal. The purpose of such waste management regulations is to minimize the potential contamination of terrestrial ecosystems (by physical littering; landfill leachate) and aquatic resources (e.g., potable water, fisheries), and to preserve human health.

Biological soil degradation

Soil biological degradation refers to the depletion of the soil organic carbon pool, loss of soil biodiversity and soil biological functions, a reduction in soil carbon sink capacity, and increased greenhouse gas emissions from soil to atmosphere (Lal, 2015).

Losses of soil organic carbon in both, intensively and extensively managed agricultural production systems are contributing to increasing greenhouse gas emissions to the atmosphere (Cloy and Smith, 2023; Lal, 2004). Gregory (2023) summarizes the symbiotic degradation of soil structure and organic matter including the main causes and effects of these processes.

Soil is considered a living organism with more than 170,000 species of soil organisms identified (Lal, 2022). These organisms play a vital role in the functioning of the soil ecosystem, its stability and sustainability. Key ecosystem services provided by soil organisms are the formation and turnover of soil organic matter including mineralization and sequestration of carbon, fixation of atmospheric nitrogen, disease transmission and prevention, and nutrient cycling. The soil biological community also modifies soil physical structure through bioturbation and microaggregate formation, thereby, contributing to water regulation in soils. Soil organisms influence plant health through their effects on pathogens, nutrient cycling and uptake.

Studies have shown that anthropogenic activities such as land-use change and agricultural intensification (irrigation, cultivation, fertilization, etc.) and climate change can reduce abundance and diversity of soil biological communities (Tsiafouli et al., 2015). However, to date, it is not well understood whether such changes in biological communities have effects on the functioning of ecosystems. High functional redundancy has commonly been proposed as an explanation for the lack of clear relationships between soil microbial diversity and specific soil functions, e.g., organic carbon mineralization (Nannipieri et al., 2003). The shifting focus from short- to long-term effects of redundancy on ecosystem functioning reveals that redundant species can buffer against environmental changes (Jurburg and Salles, 2015). More recent research highlights the role of soil biodiversity for the provisioning of multiple ecosystem functions at various time points (Mori et al., 2016; Wagg et al., 2019, 2021).

Proposed indicators of biological degradation of soil include measurements of soil biodiversity and community composition, soil enzyme activities as indicators of nutrient cycling processes, accumulation of toxic molecules, and changes in the soil redox status (Sims, 1990). Qualification of soil biota according to traits, such as cellulose degraders, has been proposed to monitor biological soil health (van der Putten et al., 2023).

Soil remediation

The final chapter by Sanderson et al. (2023) is dedicated to soil remediation following soil contamination. In the recent decades, an emphasis on sustainability is increasingly placed on remediation technologies and new remediation approaches and techniques have been developed. Broadly, remediation technologies fall into the categories ‘containment and isolation’, ‘immobilization’, ‘separation and removal’ and ‘detoxification’. Remediation of contaminated soils is a critical part of the restoration of degraded lands to safe and beneficial reuse. Remediation will not only help to restore the ecosystem environments but will also provide additional land back into the pool required to sustain human life and food security.

Abstract

Soil monitoring is required to determine where threats to soil function and health are appearing, to assess the effectiveness and sustainability of land management practices and to understand soil processes better. Many changes in soil properties are only apparent on decadal time-scales and therefore soil monitoring is a long-term commitment. Soil monitoring networks must be established with thorough and carefully recorded protocols that are cost-effective and robust to changing land uses and technological advances, and that can adapt to address evolving soil health priorities and questions. This chapter considers the many elements of such a protocol.

Key points

- Soil monitoring requires careful and long-term planning.
- The motivation for establishing a soil monitoring network must inform the protocols and design of the network.
- The network protocols must be robust to changing policy and science priorities, landscapes, organizational structures and technology over decadal time-scales.
- New technologies and measurement techniques have the potential to improve the accuracy and resolution of soil monitoring networks and the breadth of soil processes and functions that can be monitored.

Introduction

In the first edition of this encyclopedia, Loveland and Bellamy (2005) described the great commitment and considerable planning that is required to monitor the status of soils and to provide reliable information about changes that are occurring. They highlighted the need for robust protocols so that comparable soil measurements and information can be gathered many years apart and for decadal scale funding to ensure that the monitoring efforts are fully exploited. More than 15 years on, many technological advances have occurred. As standard, soil measurement sites are now reliably located using Global Positioning Systems (GPS). Advances in disciplines such as metagenomics and techniques for measuring more types of soil pollutants mean that more properties of the soil can be measured. Remote sensing methods have increased the spatial extent of soil and landscape information, whereas proximal soil sensing methods permit spatially intensive measurements. Both types of sensors have also led to an increase in the achievable temporal frequency of measurements. Furthermore, adoption of advanced statistical and machine learning techniques have aided the interpretation of the sometimes huge soil datasets that result from monitoring. However, the underlying principles from 2005 remain true. Changes in the soil can only be reliably quantified if a monitoring survey is designed according to sound statistical theory, if consistent measurement methods are used throughout the survey, if appropriate data analysis methods are applied and if all elements of the soil monitoring protocol are reliably documented. This still requires considerable and long-term financial commitment. Therefore, in this revised chapter we make only small modifications to Loveland and Bellamy's (2005) description of the methodology and principles that underpin surveys for soil monitoring. We do, however, briefly discuss how recent technological advances might improve soil monitoring and the extent to which they can compensate when the optimal monitoring procedures cannot be followed.

Underlying principles

Soil monitoring (SM) is often driven by the desire to understand soil quality and changes in it. This usually requires the establishment of soil quality indicators or properties. This can, and does, have a profound influence on what type of SM is carried out, how a program is designed and executed, and what it costs (e.g., [Black et al., 2008](#)). Effective SM implies long-term commitment and very tight control of potential sources of variability. Decisions taken at the planning stage are of extreme importance, and careful attention to them can save much money and trouble and lead to greater reliability. Two essential points are:

- There is no universal system of soil monitoring; the means must fit the purpose and vice versa.
- There is a clear distinction between a soil inventory program and a soil monitoring program.

The first point might seem obvious, but is often overlooked. What is appropriate for an industrial site and its surroundings, where potential hazards to human health might be the motivation, can be wholly inappropriate in an area where maintenance of a particular soil ecosystem is the target or at the national-scale where multiple concerns must be considered.

The second point is that an inventory is a collection of information about a place. For soils, it might be the features observed at the location of a soil profile and the properties of the profile horizons. 'Monitoring' implies temporal change, i.e., observation, sampling, and measurement repeated over time. There is thus a different intent and commitment in soil monitoring compared with an inventory, although the latter might be the starting point (baseline) of a soil monitoring program. It is stressed that a single set of measurements in time does not constitute soil monitoring.

Most commonly, soil monitoring targets change in a specific property or properties, e.g., pH, metal content, biomass. However, it can be equally important to study a process, e.g., soil erosion. Increasingly, there is a demand to understand potential soil functions ([van Leeuwen et al., 2017](#)). Linking soil monitoring to other environmental monitoring programs can maximize long-term benefits from the data collected. Planning soil monitoring needs to take these different objectives into account.

Finally, although many of the points discussed below might also apply to small parcels of land, this chapter is mostly concerned with the concept of soil monitoring applied at the regional or national scale.

Why monitor soils?

Since the turn of the century, there has been growing acceptance that not enough is known about soils and the changes that they are, or might be, undergoing, especially under increased pressure from human activities ([European Commission, 2002](#)). This contrasts with the effort that has gone into the assessment of air and water quality. There are concerns that pressures on soils, usually driven by economic needs, will lead to irreversible decline in their ability to maintain ecosystem diversity, food security, carbon storage, fiber and timber production and this will lead, indirectly, to serious problems with water and air quality and climate regulation. Thus, the whole framework of sustainable development would be compromised. There have been many statements over the last few decades pointing to the need to consider soils in terms of the:

- establishment of a set of principles for the rational use of soils and protection of them against irreversible degradation;
- pursuit of programs of soil conservation and reclamation and appropriate use of soils;
- recognition of soils as a fragile and essentially irreplaceable resource;
- importance of specific soil properties such as those that determine best use and land management practices
- need for inventories and monitoring programs to establish baseline soil properties and changes in these over time.

Against this background, soil monitoring can be instigated for a number of reasons:

- A. Basic science: are soil properties changing and, if so, where and at what rate and in what direction, and what does this tell us about our understanding of the world? For example, establishment of the magnitude of change in soil carbon content could improve inputs into models of the global carbon cycle;
- B. Political: the need for information from which to formulate, test or improve policy, e.g., conventions on transboundary pollution require reductions in the acid load to soils; this could be demonstrated by showing that soil pH is remaining above a given value over a given time;
- C. Legal: whether change has occurred to a soil that is in conflict with legislative obligations, e.g., demonstrate that loadings of so-called 'heavy metals' are within statutory limits;
- D. Financial: are the properties of a soil changing (or likely to change) over a given time-frame such that the soil is, or will become, more or less valuable in a given context, e.g., is there a potential problem from pollution that could adversely affect land that would otherwise be valuable for development.

Much of this thinking is increasingly considered in terms of the ability of soils to perform several functions, often simultaneously ([van Leeuwen et al., 2017](#)), e.g., food and fiber production, filtering, buffering, acting as a pool of genetic resource and new antibiotics, support for diversity of above- and below-ground ecosystems, keeper of the archaeological record, support for the built environment. Thus, soil monitoring is under pressure to provide information on the performance (or potential performance) of these functions and, often, to guide choices as to which set of functions should be 'allocated' to a parcel of land in preference to

Fig. 1 Change in topsoil pH between 1980 and 1995 under an arable/ley grassland rotation in England and Wales ($n = 900$) Loveland PJ (1990) The National Soil Inventory: survey design and sampling strategies. In: Lieth H and Markert B (eds) *Element Concentration Cadasters in Ecosystems*, pp. 73–80. Weinheim, Germany: VCH Verlagsgesellschaft. Data from the National Soil Inventory of England and Wales and figure previously used in Loveland and Bellamy (2005).

another, e.g., build here but not there. The measurement of properties is often no longer the absolute *raison d'être* of soil monitoring, although it is often the baseline. Fig. 1 shows that over 15 years the pH of topsoils (0–15 cm) increased under arable/ley grass rotation in England and Wales, i.e., the soils became less acid. This finding has been interpreted (Kirk et al., 2009) as a mixture of the reduction in acid deposition (policy response), better targeting of the use of agricultural lime (improved agronomic practice), and deep plowing into less acid subsoil because of larger, more powerful farm machinery (economic driver). All these reasons can be viewed as useful outcomes of soil monitoring and could lead to more focused targeting of future environmental research.

The starting point

Whatever the driver for soil monitoring, some fundamental questions need to be addressed (e.g. Black et al., 2008):

- A. What information is already available about soil type(s), properties, scale of observations, etc.?
- B. Is this information internally consistent, e.g., are, or were, all the data obtained in the same way, or in ways comparable enough for the purpose intended?
- C. What information is not available and does this matter?
- D. At what spatial and temporal scale is further information required?
- E. Is information required simply as values of a property, or in ways that describe soil functions; if so, which function is of greatest interest?
- F. What is the target, e.g., all soils in an area, the common soils, rare soils, a specific ecosystem, a specific soil process?
- G. What magnitude of change is of interest, over what time scale, and is this a realistic target?
- H. Is the property measurable or is further research needed?
 - I. Is it necessary to collect more information, or can the need be met from surrogate measurements, pedotransfer functions or from extrapolation, interpolation and classification of existing data?

Organizational and practical questions arise:

1. How can soil monitoring yield the greatest amount of information for the greatest number of people for the least cost?
2. At what time interval is the monitoring to take place?
3. Is this interval suitable for all soil properties of interest?
4. Can the needs of the users be satisfied with one soil monitoring design, i.e., number and layout of sites; if not, what modifications are needed?
5. Will one organization do everything, or is it to be a consortium (if so, who leads?)
6. Does the lead organization have the ability, infrastructure and will to keep that role for a sufficient period? It is no use setting up a 10-year program if those involved drop out after 5 years;
7. Are there agreed protocols for the design of the monitoring network, for the location, layout, and description of sites, for the soil sampling, for the preparation and storage of samples, for laboratory work, for quality control; if not, who will orchestrate this?
8. Who will keep the samples, the raw data, the processed data, and be responsible for them into the future?
9. Who 'owns' the data, i.e., are there issues of copyright, intellectual property rights, confidentiality, and controls on the release of data?

10. Is there an agreed publication policy for the output from the soil monitoring, given that many years might pass before sufficient data are available to allow robust statements to be made about change?
11. What will the various options cost, bearing in mind that the costs of very long-term site maintenance, quality control, and storage can be substantial?
12. Will the monitoring sites remain accessible in the future (urbanization, site access)?

Many of these points might seem trivial. However, the time scale over which soil monitoring must run before large amounts of meaningful data are acquired has to be seen in decades. Thus, the objectives, responsibilities, targets, and costs need to be thought through with great care and appropriate commitments obtained.

Soil monitoring networks

Many countries have conventional soil survey maps showing the spatial distribution of soil types. Although the scale of the map controls the smallest area of any soil type that can be shown, even relatively coarse-scale maps, e.g., 1:250000 scale, can indicate the relative abundance of soil types. At a very early stage, it has to be decided whether the soil monitoring network is to be capable of sampling rare soils, i.e., those occupying only a small proportion of the landscape. As a guide, a network that is expected to 'capture' a soil occupying 5% of the landscape with 95% confidence would need several thousand sampling locations (Table 1). An example is the National Soil Inventory (NSI) for England and Wales (UK; approx. 150,000 km²), which sampled almost 5700 points on a regular grid, but only captured about 400 of the 700 soil series that are known to occur in the two countries (Loveland, 1990). If no soil maps exist, then the problem becomes even more pressing.

Numerous designs (see examples in Fig. 2) have been proposed for national or regional soil monitoring networks (Arrouays et al., 2012). The NSI network is based on sampling at the intersections of a 5 km × 5 km-square grid. The Forest Soil Monitoring Network in Europe is based on a regular 16 km × 16 km grid, and there are many other examples of the use of square grids. The most efficient regular geometric grid is triangular, but the square grid has traditionally been favored because it can be co-located easily with a national geographic grid, thus making it easy to find points on the ground using conventional maps. This provision has become less important with the common use of GPS. One caution often expressed about square grids is that the periodicity of the grid might match that of some periodicity of the soil itself. However, whilst this might be true at the field scale, e.g., rows of crops in orchards and olive groves, 'tramlines' in arable crops, etc., no evidence has yet been presented that such periodicity exists for very

Table 1 Size of random sample required (*n*) to estimate the proportion (*P*) of soils of a specified type within limits $P \pm 0.1P$ for three levels of confidence, calculated from the normal approximation.

<i>P</i> or $1-P$	<i>Confidence Limits</i>	<i>n</i>		
		80%	90%	95%

Fig. 2 Realizations of different spatial sampling designs: (a) a 36-point regular square grid, (b) a 36-point unaligned design, (c) a 32-point stratified random sample (strata are the marked squares) (d) a 32-point simple random sample.

large areas of land. In situations where periodicity could be a concern, an unaligned sampling might be used. According to this design, each cell of a regular square grid is sampled once but the position of the measurement within the cell is varied. The y-coordinate of any one column and the x-coordinate of any one row are selected at random and fixed for that column or row. The design ensures that measurements are reasonably evenly dispersed across the study area but they are not aligned to any periodic features.

Alternatively, networks can be designed based on a probabilistic selection of points. Simple random sampling can be inefficient as the points might not be evenly dispersed across the study region. This issue can be partly addressed by stratifying the sampling according to spatial sub-regions or according to covariate information such as soil classes. The Soil Sampling Programme (SSP) for the Netherlands implemented a stratified random sampling approach. The primary stratification was based on water table depth and pedologically homogeneous classes (Knotters et al., 2022).

The pros and cons of systematic and probabilistic designs have been widely discussed (e.g. de Gruijter et al., 2006; Black et al., 2008; Arrouays et al., 2012). In summary, data collected from probabilistic designs are amenable to classical statistical analyses leading to unbiased and valid estimates of the mean across reporting units and quantification of the uncertainty of these estimates. In contrast, systematic designs cover the study region more efficiently and are well suited to geostatistical analyses and mapping of the resultant data. However, model-based techniques must be used to analyze data from systematic designs and these techniques require the practitioner to make assumptions about the statistical distribution from which the measured values are realized and the correlation between measurements from different sites.

An alternative design approach is weighted or purposive sampling, i.e., the sampling points are located on the basis of, for example, an existing network of sites such as experimental farms, sites for other forms of monitoring, selected soil-landscape combinations or, possibly, perceived soil functions. The principal problems with this approach are:

- It might not yield enough points to allow the spatial structure of the data to be estimated reliably by geostatistical methods—too much of the landscape is omitted;
- There is a high risk of introducing bias into the estimation of the statistical parameters.

However, such schemes can yield reliable baseline data for particular soil properties, e.g., lead content, provided that the limitations are appreciated. Well-conducted monitoring networks of this kind are being run, for example, in Switzerland, Austria, The Netherlands and France (Saby et al., 2017) among others.

Protocols

Whatever is done and by whom, it is absolutely essential to have protocols in place for all aspects of the work: site selection, accuracy of location, sampling strategy at each site, sampling, sample treatment in field and laboratory, analytical procedures, data storage and handling, and data access. Uncontrolled sources of potential variability are the enemy of long-term monitoring. Peoples' memories are not reliable over long timescales, and there is no certainty that those people will be available some years later to answer any questions. Information including meta-data, sampling protocols and perhaps photographs must be stored securely in digital repositories and proper recording and training undertaken. Above all, it is vital that information is shared between investigators to ensure safe long-term storage.

Technological developments might lead to improvements in protocols over time. For example, more accurate methods of measuring soil properties could be developed. Careful thought must be given to adopting these advances in later rounds of a SM network. The improved accuracy must be weighed against difficulties in comparing measurements made according to different protocols. If protocols are changed then archived samples from previous sampling rounds should be analyzed according to the new protocol, or new samples should be analyzed according to the previous protocol, to determine whether adjustments should be made to the new measurements.

Monitoring sites

Whatever design of survey is chosen, it is important to avoid bias in the exact location of measurements within a sampled site i.e., the person on the ground should not be allowed to pick and choose where to locate a soil core and how to sample.

The number of sites (n) should be sufficient to estimate the status of each soil property for each round of sampling and its rate of change between sampling rounds. However, the precision of an estimate of this status or rate of change depends upon the standard deviation of these quantities which are unknown until the data have been collected and analyzed. Hence, it is not possible to guarantee the precision of a monitoring survey prior to sampling. Furthermore, the standard deviation of change cannot be determined easily from a single sampling round (Lark, 2009). This means, that it is not possible to guarantee that resampling a specified proportion of an existing baseline survey will lead to an estimate of the rate of change with sufficient precision. A limited reconnaissance survey could be conducted to determine the relevant standard deviations and the required number of sites but, more usually, plausible modelling assumptions are used to simulate soil property data upon which different sampling designs are tested. For instance, Saby et al. (2008) used simulated data which indicated that for almost all national-scale SM networks in Europe, the

minimum detectable change in soil organic carbon stocks is greater than the annual greenhouse gas emissions. Therefore, a length of time of about 10 years between sampling rounds would be required to detect change in most countries.

In general, the rate of change in soil properties is established efficiently if the same sites are revisited in each round of the survey. However, it is important to ensure that non-representative land management practices are not applied at these sites because they are known to be part of a monitoring network and to influence the results of the survey deliberately (e.g., if a land manager is aware that rewards for environmental stewardship will be determined based on soil health metrics at specified sites, [de Gruijter et al., 2016](#)).

Although it might be possible to control activities at a small number of key sites, it is uncommon to be able to tie land owners or managers to particular land-use agreements for decades. Thus, sites can be built upon, become dumps for waste, become polluted and thus unacceptably dangerous to work on, or the land use might change so drastically that the site is no longer fit for monitoring purposes or cannot be accessed. The latter is always difficult to assess. Some would argue that if a soil is converted from arable to woodland, monitoring the progress of that change is a matter of considerable interest. Others might argue differently because they want to know how cultivated land behaves in the long term. Whatever is decided, there is a need to avoid the situation whereby the loss of a relatively small number of sites compromises the whole network. To use the example from England and Wales (UK), approximately 3% of the c. 900 sites under arable/ley grassland in 1980 had been lost to agriculture by 1995. This change was interesting in itself, but the 'loss' of these sites did not seriously alter the conclusions drawn from the data for the remaining sites (approximately 870). It is also strongly recommended that the network should have sufficient points to be robust to these losses of sites.

The simplest site is a sampling point, a spot on the ground located to a given accuracy. Points need to be located geographically according to a protocol that fits the purpose of the network. Experience has shown that people with some background of field work, using good topographic maps (1:10000 or 1:25000 scale) and/or aerial photographs, can easily relocate a point to within 10 m of a target point. With GPS, relocation to within less than a meter is possible, although nearby buildings, trees, and hilly ground can seriously distort signals. It can be valuable to mark these points to aid future relocation. A vandal-proof approach is the burial of either a metal plate (a sheet of aluminum alloy approximately 25-cm square and 5-mm thick) or of a small but powerful permanent magnet (wrapped in a plastic bag) at approximately 50-cm depth, i.e., well below plow depth. These can easily be found again after many years by appropriate hand-held, electromagnetic detectors.

There are many alternative arrangements of kinds of sites. Two of the most common are:

- Area-based sites, in which it is sufficient for the purposes of monitoring to analyze composite samples of soil that are representative of an entire parcel of land (e.g. [Oliver et al., 2006](#)). This approach is quite common in what might be termed 'agricultural monitoring,' where the argument is that fields or other parcels of land are subject to such intense management that the whole parcel becomes the site;
- Key sites or control sites that are specifically managed to be available for revisiting in the long term. An area of relatively uniform soil is identified (often of a hectare or more) and sampling plots are laid out across it in sufficient number to allow resampling according to a strict protocol that avoids resampling of previous plots for many years. These kinds of sites can be extended to allow investigation of large-scale processes such as soil erosion or the effects of afforestation, etc., but it is axiomatic that large sites, with their (partial) dedication to the long-term study of specific soil processes are expensive to run. In most countries, therefore, that have followed this thinking, the number of such sites is small (10–15 is not uncommon).

There is a belief that a small number of such key sites should be a component of any soil monitoring network as they can form a framework by which the quality control of a much larger network can be achieved.

Soil sampling

There are two key questions to be asked when considering soil sampling:

- Which soil layers are to be sampled, e.g., soil horizons (the people doing the sampling need to be able to recognize these) or fixed-depth sampling, and are litter layers to be included?
- Is the sample to be taken at a point, e.g., from the face of a soil pit or with an auger, or is it to be a bulked sample (of how many cores?) taken using the geographic point as a centroid?

In practical terms, often a combination of these approaches is used. Surface layers are readily sampled around a centroid, e.g., 25 subsamples at 4-m intervals on a 20 m × 20 m grid, a 'random' walk across a parcel of stated extent, subsampling along the radii of a circle, or a numbered layout of sufficient sampling plots to allow a considerable number of resamplings without the risk of revisiting disturbed soil. There is much to be said for this 'bulkied' approach as at least a partial answer to dealing with the short-range spatial variation of soils. Others argue for a formal, geostatistical approach to each site, so that the structure of its spatial variation is known and an appropriate sampling scheme drawn up. This can, however, have large cost implications if it is to be applied to hundreds of sites. Whatever is done should not compromise future sampling—the temptation to remove the whole of the topsoil layer at the centroid should be resisted; similarly, soil pits should be small.

Finally, the sample must be big enough, because there are usually several people who want some of it. At least 2 kg on an air-dried, less than 2 mm basis is a useful target for present and future analyses. However, the French national soil monitoring survey

has sometimes found that 5-kg samples are insufficient to support all potential research activities. Even a mass of 2 kg has implications for the volume of organic (peat) soils sampled. Sample storage needs considerable prior discussion with all who might have an interest, e.g., the chemists might be happy with dried material, but what do the biologists want? Long-term 'fresh' sample storage implies access to specialized facilities—Do they exist? Can they handle the number of samples (this year, next year, every X years, etc.)? Storage of frozen samples can pose similar problems. Air-dried material can be stored in screw-cap glass bottles with Teflon lid liners (but these can be costly). Special consideration should be given to the storage of samples for microbial analysis (e.g., [Schroeder et al., 2021](#)). The amount of shelf space required for the next 10, 20, 50, etc. years needs to be estimated, as well as the cumulative weight of the material. An intelligible sample-identification system is required so that samples can be retrieved, and a mechanism is necessary that ensures no one arbitrarily moves the samples or throws them away.

If the physical properties of soils are of interest, e.g., bulk density, aggregate stability, water-retention characteristics, and hydraulic conductivity, then other sampling techniques are required (e.g., undisturbed cores or samples of known volume) that are best discussed with the appropriate specialists. It might be necessary to designate a separate area of the site for this kind of work, as considerable disturbance can be involved. Above all, it is necessary to allow for sufficient sampling space to accommodate all potential measurements without compromising any of the others.

Quality control

This is not just a laboratory matter, but applies equally well to field operations. Whichever is under consideration, protocols, testing, and training are paramount; slipshod procedures at any stage can undermine the whole enterprise.

In the field, there is much to be said for having a formal recording system—the site location, local land characteristics, aspect, slope, etc. being recorded in standard ways, and (permitted) deviations from these should be recorded also. For example, it is common to find that the specific geographic point is not accessible (e.g., because it is covered by a road or building). Rather than abandon the site, limited, structured deviation is permitted, e.g., move 100 m north, then east, then south, etc., the details of the deviation being recorded. Such information can be recorded on proformas on portable computers.

Long-term quality control requires that a proportion of the samples are analyzed in duplicate or triplicate during the current program and during every subsequent resampling. This is to detect long-term drift. The proportion is a matter for discussion, but, as the monitoring program continues, the amount of 'repeat' analysis becomes the largest component of the laboratory work, with implications for costs. If samples are to be sent to distant laboratories, a system has to be established for this. For example: Are field refrigerators or 'cool boxes' required? How quickly should the samples be sent (overnight for biological monitoring)? Does the laboratory know what to do when the samples arrive? Protocols have to be set up for all these matters and tested before the monitoring commences, e.g., can the protocol deal with samples arriving at the start of a public holiday?

Ideally, all the determinations should be made in one laboratory but, even where this is not possible, thought should be given to dividing the work into blocks, e.g., all the metals are determined in one laboratory, all the organics in another, all the biology at a third. Are the chosen laboratories up to standard and are they familiar with soils? Do they have formal QA procedures in place and are they accredited and audited? Do they use widely recognized standard methods (International (ISO) standards should be used wherever possible)? Are they viable in the long term? Cheapest is not necessarily best.

Similar approaches are necessary with regard to output from the soil monitoring program. The data need to be held securely in a system that has a good prospect of long-term stability in terms of software and staffing. Data ownership, intellectual property, personal data regulations and related issues need to be clarified at an early stage, as does a policy over the publication of results.

Recent developments in soil monitoring practices

More than 15 years after Loveland and Bellamy's original encyclopedia article, the need for soil monitoring is undiminished. A harmonized framework for soil monitoring in Europe is one of the four pillars of the "Soil Deal for Europe" European Union Mission ([Panos Panagos et al., 2022](#)). Emphasis continues to be placed on monitoring the capacity of soils to (often simultaneously) perform vital functions such as primary production, water purification and regulation, carbon sequestration and climate regulation, soil biodiversity and habitat provisioning and recycling of nutrients. Soil pollution by metals remains a major concern and many more chemical contaminants are being monitored (e.g. [Froger et al., 2021](#); [Yu et al., 2020](#)). However, within Europe, the data from broad-scale soil monitoring networks are unbalanced both geographically and in terms of the functions that can be assessed ([van Leeuwen et al., 2017](#)).

In recent years, considerable emphasis has been placed on monitoring the amount of carbon stored in soils. Land managers and policy makers need to understand better the circumstances in which soil carbon sequestration can be achieved in order to limit the amount of carbon dioxide in the atmosphere and the rate of increase of global temperatures. However, [Saby et al. \(2008\)](#) note that the minimum detectable change in carbon stocks for almost all European SM networks is greater than annual greenhouse gas emissions and therefore it is unlikely that these networks can be used for annual carbon accounting. It would take at least a decade to address these shortcomings of current SM networks and to estimate the rate of change of soil properties based on two rounds of sampling. Therefore, alternative approaches are being sought.

Recent reviews (e.g. Arrouays et al., 2012; Filippi et al., 2016) of soil monitoring activities emphasize the use of legacy data that was not collected for SM purposes. Information about the rate of change of soil carbon stocks, for example, can be obtained by resampling sites where measurements had been made previously or by examining trends in databases of soil measurements such as those collected to inform agricultural management practices. However, as described in relation to purposive sampling above, the absence of a statistical design for these data sets means that biases can occur and novel statistical methodologies (Saby et al., 2017) and accompanying model assumptions are required to make appropriate adjustments.

Information on soil carbon accounting is required across spatial scales to understand both the impacts of activities within a single field and the accumulative effect across a landscape or nation. National-scale soil monitoring networks are not suitable for determining farm-scale trends, but advances have been made in the design of sampling schemes to enable efficient measurement of soil carbon trends at this scale (de Gruijter et al., 2016) and in the use of proximal sensors to predict soil carbon stocks. For example, Viscarra Rossel et al. (2017) developed a soil condition analysis system that analyses soil cores within the field and includes a γ -ray attenuation densitometer to measure bulk density and a visible-near-infrared sensor to determine soil carbon concentrations through the use of machine learning algorithms.

The potential to use remote sensing for large-scale assessments has also been explored. In contrast to the multi-year intervals between phases of a soil monitoring network, optical satellite data can be obtained approximately weekly (unless prevented by cloud cover) and used to monitor quantities such as soil moisture or soil carbon (Angelopoulou et al., 2019; Babaeian et al., 2019). The quantities of interest are often not directly measured by the sensors but inferred from other quantities in conjunction with statistical or machine learning models. The quality of the calibration of these models, which can possibly vary in both time and space, can lead to an additional component of uncertainty in the inferred trends. In addition, although there is some evidence that the soil carbon content of bare soils can be inferred from remote sensing data, vegetation, crop residues and variable soil moisture conditions can all confound the models that underlie these predictions (Environmental Defense Fund and Woodwell Climate Research Center, 2021). Smith et al. (2020) advocate a soil carbon monitoring, reporting and verification system that integrates information from short- and long-term experiments, process models, spatial data, activity data (e.g. details of farm management practices), remote sensing and soil monitoring networks.

These approaches potentially increase the temporal and spatial resolution at which the soil can be measured, but it is vital that the principles of reliable soil monitoring described in this chapter are not forgotten. Practitioners must consider whether the sensor measurements are truly representative of the relevant soil property at the appropriate spatial-scale. Care must be taken to ensure that measurements made at different times are truly comparable and the approaches used to analyze the data must be thoroughly documented.

Summary

Soil monitoring programs need to be 'fit for purpose'. At the start, a clear answer to the question 'Why are we doing this?' is needed. Considerable planning is required to achieve success. A large number of issues need to be considered and decided at an early stage and written into robust protocols. Above all, soil monitoring has considerable spatial, temporal, and cost implications, and there has to be a commitment at the decadal scale. Novel remote and proximal sensing technologies offer opportunities to observe the state of soils more frequently, but only if these basic principles underpinning reliable soil monitoring are followed.

Abstract

The concepts of soil quality and soil health concern the ability of soil to function and provide ecosystem services. This chapter reports a historical and critical overview of the two terms and a review of the methods and indicators currently used to assess and monitor soil quality and health. Different approaches are described and guidelines on the selection and use of indicators across spatial and temporal scales are provided. Key indicators are introduced, grouped according to their relevance to provide 10 specific soil functions, with their main references, sensitivity to changes, and relative cost of sampling and analysis.

Key points

- The passage from the concepts of soil fertility to soil quality and soil health.
- Main principles in the use and selection of soil indicators.
- Considering spatial and temporal variations.
- Most commonly used soil quality and health indicators.

Introduction

Water and air quality are usually assessed considering their degree of pollution, as it impacts directly the health of humans and animals, and natural ecosystems. The soil quality concept is more complex, not only because soil encompasses solid, liquid, and gaseous phases, but also because soils can be used for a larger variety of purposes. Soil quality is not limited to the degree of soil pollution but is commonly defined much more broadly as “the capacity of a soil to function within ecosystem and land-use boundaries to sustain biological productivity, maintain environmental quality, and promote plant and animal health” (Doran and Parkin, 1994 in Bünemann et al., 2018). The quality of soils determines agricultural and forestry sustainability, environmental quality and, as a consequence, plant, animal, and human health. Changes in soil quality over time can be due to natural events or, more often, to human use. Assessment of soil quality by the use of indicators is then mandatory to inform policymakers, farmers, and citizens about the impact of human activities on soil and its functions.

From soil quality to soil health

Historically, the term “soil quality” has been strictly related to the concept of land evaluation to support primary production. Indeed, the soil ecosystem service that was first considered by humanity was the production of food, feed and fibers, therefore assessments of the suitability of a soil for crop growth may have been taken into account since the origin of agriculture. Before the introduction of the term soil quality, the concept of “soil fertility” was used to describe the capacity of the soil to provide water and nutrients for plants. The FAO (Food and Agriculture Organization) described soil fertility as “the ability of the soil to supply essential plant nutrients and soil water in adequate amounts and proportions for plant growth and reproduction in the absence of toxic substances which may inhibit plant growth” (<http://www.fao.org>).

Although soil fertility is a basic concept that refers to the function of biomass production, the soil provides several other functions, important for ecosystems and human well-being. Another term has been then introduced, namely “soil functionality,” which means the ability of a soil to provide functions and ensure the provision of the various ecosystem services. The European Commission published the communication “Towards a Thematic Strategy for Soil Protection” (COM 2006.231) where seven soil functions have been defined: (i) production of food and biomass, (ii) storage, filtering and transformation of compounds, (iii) habitats for living creatures and gene pools, (iv) physical and cultural environment, (v) source of raw materials, (vi) carbon pool, and (vii) archive of geological and archeological heritage.

To summarize, soil properties determine the soil functionality, that is the ability to produce functions that grant ecosystem services. The concept of “soil quality” is closely related to functionality, but it emphasizes the multi-functionality behavior of the soil, and it is related to land use. The better is the soil quality, the greater are the functions that the soil can perform optimally.

The need to assess the quality of soils at a certain scale, from continental scale to single farm, is mainly linked to the monitoring of the effects of human activities on soil resources. In the history of humankind, humans have often neglected the soil more than other natural resources, and this lack of awareness resulted in failures and the end of civilizations, namely the Maya in Central America, Vikings in Iceland, Rapa Nui people in Easter Island, and Mesopotamian civilizations. More recently, the catastrophic failures in land management of the 1930s in the United States began with ignorance of the Great Plains’ soil resource, which was described as “indestructible and immutable” in the 1909 Bureau of Soils Bulletin.

Efforts to define and assess soil quality can be traced to publications from the 1960s to the 1970s. One of the oldest mentions in the scientific literature is by Klingebiel and Montgomery (1961), who defined soil quality as “an attribute of a soil that cannot be measured directly, but which is deduced from soil properties and soil behavior under defined conditions. Fertility, productivity, and erodibility are examples of soil qualities.” Later, Mausel (1971, in Bünemann et al., 2018) when soil mapping in Illinois (United States), defined soil quality as “the ability of soils to yield corn, soybeans, and wheat under conditions of high-level management.” It is clear that, historically, the concept of soil quality matched with “land capability,” defined as the intrinsic capacity of a soil to contribute to agricultural production. The high-quality soils or “prime farmlands” were the soils of the first two classes of land capability, while the last classes were those only suitable for more or less productive forestry and pasture or just for ecological purposes (Klingebiel and Montgomery, 1961).

Doran and Parkin (1994 in Bünemann et al., 2018) considered the focus on agricultural productivity to be too restrictive and proposed that soil quality should be disconnected from productivity. Besides agricultural productivity, the soil quality concept should include the ability of soils to contribute to environmental quality and to promote plant, animal, and human health. In 1993, the U.S. National Research Council (NRC) published an agenda for U.S. policymakers, titled “Soil and water quality: an agenda for agriculture”, which stressed the importance of soil quality and its application in land management. The agenda reported that national policies should not only focus on controlling erosion and conserving agricultural productivity, but they should also consider other threats to soil quality, namely salinization, compaction, acidification, and loss of biological activity. In the same year, the U.S. NRC also established the Soil Quality Institute (SQI), with the mission to develop tools for soil quality assessment. During the 1990s, one of the first methods used to assess soil quality was through the development and use of soil quality scorecards. In 2001, the U.S. Department of Agriculture published the first guidelines for “Soil Quality Assessment in Conservation Planning,” where a series of indicators and a field record were proposed.

Sojka et al. (2003) (in Bünemann et al., 2018) criticized the “soil quality” paradigm, expressing dissatisfaction with the idea of a universal soil quality index and with the formal adoption of soil quality evaluation. They also affirmed that soil quality lacks standards and oversimplifies the complex interactions occurring in soil, therefore the concept of “quality of soil management” should be preferred. Although their proposal did not find much support in the scientific society, their criticisms have influenced the development of soil quality evaluation, in which soil management has become central. Soil quality assessment should provide scientific tools to evaluate the management of soil resources, considering not only biomass production but also other ecosystem services provided by the soils (Bünemann et al., 2018).

The original concept of soil quality is continuously evolving and recently has often been replaced by “soil health,” to emphasize the behavior of the soil to be a dynamic living resource. Some authors consider the terms “soil health” and “soil quality” to be equivalent and interchangeable, while others differentiate the meaning of the two words. Soil quality is related to soil functions or what it does, while soil health presents a holistic view of the soil as a dynamic living resource (Lehmann et al., 2020). Soil health has also been illustrated as an analogy to the health of an organism or a community. More specifically, soil health has been defined as the “capacity of soil to function as a vital living ecosystem that sustains biological productivity, maintains environmental quality and promotes plant, animal, and human health” (Doran and Zeiss, 2000). Recently, the FAO Technical Group on Soils (ITPS)

defined soil health as “the ability to sustain productivity, diversity and environmental services of terrestrial ecosystems” (<http://www.fao.org>).

Soil health should be maintained, promoted, or recovered through the implementation of sustainable soil management practices. In recent years, several foundations with the mission to promote, safeguard, and enhance soil health through scientific research and advancement have developed in several countries of the world, often supported by their governments. Policymakers have increased awareness of soil health and its importance for the environment and human health. In addition, some major companies are starting soil health programmes to manage their supply chains more sustainably.

In 2012, member countries of the FAO established the Global Soil Partnership (GSP) as a collaborative mechanism to ensure soil governance and promote sustainable soil management (SSM). The GSP is developing technical and policy tools to adapt the principles of sustainable soil management to local needs and stakeholders, as well as to encourage investment in technical cooperation, education, and awareness (<http://www.fao.org>). After the International Year of Soils 2015 and the revision of the World Soil Charter, the GSP published the Voluntary Guidelines for Sustainable Soil Management (VGSSM). The VGSSM has been aimed at being a reference that provides general technical and policy recommendations on SSM for a wide range of stakeholders, including governments, forest and land managers, agricultural advisors, farmers, civil society and academia. In 2020, FAO-ITPS (<http://www.fao.org>) published the “Protocol for the Assessment of Sustainable Soil Management,” where they reported the recommended indicators and the approaches to evaluate SSM. A farmer-to-farmer training system, called the “Global Soil Doctors programme” was also developed by the GSP in 2020. The programme aims to educate farmers on sustainable soil management and the preservation of soil health through a set of tools including educational material, a soil testing method (STM), and a soil testing kit (STK) for preliminary soil analyzes (<http://www.fao.org>).

The European Union has also adopted the term soil health. In a recently published document entitled “Taking Care of the Soil is Taking Care of Life” soil health is defined as “the continuous capacity of soils to provide ecological functions for all forms of life.” The document puts soil at the center of the actions to be taken to achieve the sustainable development goals set by the European Green Deal (https://ec.europa.eu/info/publications/caring-soil-caring-life_en).

Different approaches on soil indicators: Quantitative and qualitative, field and laboratory analyzes, visual assessments

Assessment of soil quality and health indicators (SQI, SHI), and monitoring the direction of change with time, are fundamental to determine the sustainability of land management and to verify the effectiveness of the strategies for conservation management practices. An important aspect to take into account for soil quality assessment is the identification of a set of indicators or attributes that are sensitive to changes in land management, which influence the capacity of a soil to fulfill its functions. Such indicators can be assessed using qualitative or quantitative techniques and should be easy to measure as well as sensitive to variations in climate and management (Bünemann et al., 2018). Approaches that target farmers and stress the educational aspect usually involve qualitative or semi-quantitative indicators, which can be easily assessed in the field, deliver rapid results, and facilitate communication between farmers and scientists (Fig. 1).

Standardization of the methods to collect and group indicators is also fundamental, although monitoring soil quality is usually planned with specific goals and areas of the study. For example, specific studies on soil quality have been made to evaluate the effects of tillage types in croplands, different types of agricultural management of extensive agricultural areas, land-use change, and

Fig. 1 Graphical sketch to summarize how the different soil concepts, namely soil health, quality, and fertility, are affected by the scale and methods of assessment. On the right, how the different concepts are relevant for soil ecosystem services. The figure was inspired by the sketch of Lehmann et al. (2020).

urban soils. The reliability of SQIs mainly depends on their ability to represent the spatial and temporal variations within a certain study area. Therefore, it is difficult to find a universal approach to evaluate soil quality worldwide and in all situations. Increasing awareness of soil resources and national regulations have catalyzed a proliferation of various SQI and SHI, guidelines, and scorecards for field surveys. Among the different approaches, qualitative methods based on direct visual assessment of field indicators are the most rapid, easy, and cost-effective. One of the most widely used worldwide is the Visual Soil Assessment (VSA), proposed by the FAO to assess soil quality worldwide, which is based on the visual appraisal of key soil “state” and plant performance indicators. The VSA guidelines have been developed for general land cover categories (annual crops, pastures, orchards) and some specific crops (maize, olive orchards, vineyards, wheat) (<http://www.fao.org>).

Another widely used visual method is based only on soil physical characteristics, and it is called Visual Evaluation of Soil Structure (VESS) (Franco et al., 2019). This method is included in the “spade methods” as it involves the sampling of an undisturbed soil slice 0.25-m deep, 0.1-m thick and 0.2-m wide using a straight spade. The VESS scorecard includes the evaluation of structure quality, consistency, aggregate-size distribution, porosity, and roots frequency.

Visual methods are important because they can be included among the techniques of citizen sciences, as they can be executed by non-experts of the soil. On the other hand, visual soil assessment alone cannot fully evaluate the state of ecosystem services driven by biological, chemical, and hydrological soil processes. A combination of visual assessment and low-cost laboratory analysis is needed to improve soil quality determination.

In the United States, the Cornell Soil Health Test offers various soil health testing packages for farmers and policymakers. Furthermore, the U.S. Department of Agriculture developed the “Cropland In-Field Soil Health Assessment Guide” as a qualitative diagnostic tool for field use to help U.S. conservation planners. The guide includes 11 indicators that can be easily monitored in the field to assess the impact of soil management on croplands.

In addition to the qualitative methods described above, quantitative methods to assess soil quality have also been proposed. To capture the overall state of the soil, quantitative methods usually have complex and multivariate approaches, such as “least square regression” models. In some cases, the measurement of a specific soil feature can be relatively time-consuming and becomes impractical to analyze in the laboratory. In that case, the literature has reported several pedotransfer functions (PTFs) to estimate some soil parameters through the measurement of basic soil properties, which are easier to analyze and are often available in the soil databases. The PTFs are frequently used to estimate the hydrological properties of soils, in particular, saturated permeability (K_{sat}) and available water capacity (AWC), but others have been developed to estimate many other properties, like oxygen diffusion coefficient and cation exchange capacity (CEC).

Importantly, the soil classification and taxonomic systems, such as the World Reference Base (IUSS Working Group WRB, 2014), and Soil Taxonomy (Soil Survey Staff, 1999) are not only based on soil genetic processes but also characteristics related to soil fertility and quality. Soil evaluation based on soil classification has been conducted for many purposes, such as assessment of soil productivity (Eswaran et al., 1997, see Bünemann et al., 2018), cadastral quality and value of soils (Sapozhnikov and Granina, 2021), as well as soil quality in urban environments (Makki et al., 2021). Therefore, the type of soil can be used as an indicator of soil quality, with different possible interpretations according to the detail of the taxonomic level. Soil classification systems usually focus on the subsurface horizons in addition to the topsoil, therefore, soil types are better indicators of slowly changing environmental conditions.

Selecting indicators

Many frameworks exist for soil quality and health assessments, and they are characterized by various indicators and their aggregation. Such indicator frameworks can be divided into three groups concerning their main focus: (i) assessing soil quality of a certain territory, based on detailed field measurements or by soil database and associated models; (ii) comparing the impact of different soil management systems; (iii) elaborating on the status of specific soil threats. In addition, the selection of indicators should be made based on the type of land of interest: croplands, forests, polluted soil, etc. A review by Bünemann et al. (2018) reported the frequency of the indicators used in the literature. The most commonly used to assess soil quality and health are soil organic carbon/matter, pH, available phosphorus and potassium, total nitrogen, water storage, and bulk density. Other indicators are less commonly used because of the difficulty and/or costs of the measurement, for example, labile organic carbon, soil respiration, microbial biomass, earthworms, and micronutrient availability. Further indicators are used to assess the state of specific threats, for example, sodicity–salinity for salinization processes, or presence of contaminants. The technical literature reports a long list of possible soil indicators, and there is no general agreement about the ones to use in the different national legislations and policies. In some cases, indicators are grouped in a comprehensive soil quality index equation, after the application of weight factors provided by the experts.

A possible strategy is the setting of a minimum dataset to overcome problems like costs of measurements, collinearity, as well as excessive complexity of the relationships between indicators and management options (Bünemann et al., 2018). Selection can be carried out through a statistical data reduction by multivariate techniques such as principal component analysis (PCA), redundancy analysis (RDA), and discriminant analysis. A selection of a minimum dataset of soil indicators is also recommended by the FAO, the Soil Quality Institute, and the EU expert panel, while larger datasets are advised for specific purposes.

Interestingly, some methodological approaches include features of soil health indicators that are not directly related to soil characteristics. For example, the FAO protocol includes the evaluation of soil productivity through the weight of the total biomass or

an estimate of the dry biomass per unit area. The EU expert panel includes vegetation cover and soil sealing in the minimum dataset, because of their direct impact on soil health in farmland, forestry, and urban settings. The Implementation Plan of the Soil Deal for Europe also considers landscape heterogeneity and forest cover (<https://ec.europa.eu/>). The inclusion of landscape features within soil indicators shows the attempt to use indirect traits of soil health that can be monitored through remote sensing, such as satellite images. A recent approach in assessing the effectiveness of management strategies is by combining analysis of the spatial pattern of vegetation with qualitative soil surface indicators. This simplified but effective methodology allows the monitoring of variation in landscape functioning in space and time, and it is particularly suitable for the assessments carried out at intermediate territorial scales (Costantini et al., 2016).

Soil indicators across spatial and temporal scales

The soil information needed to assess and monitor soil quality and health depends on the spatial and temporal scales. The area of consideration can be punctual like a site on a landscape, a small research plot, etc., or as large as a nation or a continent. The reliability of broader-scale assessment will depend strongly on the quality of the database in terms of the spatial distribution of observations and quality of the data, as well as on the efficiency of models to interpolate the data in the area of interest. Two approaches that deal with spatial scale have usually been used by researchers (Fig. 2). The first is based on the selection of the most sensitive set of indicators, the method of their aggregation, and the spatial distribution, for the geographic scale for which soil quality assessment is performed. In general, broader scales will include easier, more economic, and less precise indicators than detailed scales. In this approach, the quantity of data is more important than the quality, because the interpolation is data-driven. The second approach is based on precise and detailed punctiform measurements that can be expanded to a larger area of investigation by combining interpolation and extrapolation models. This approach is more costly but provides more detail on

Fig. 2 Deployment of the monitoring sites. After the selection of the covariates for spatial interpolation, they are grouped and used for the deployment of the monitoring sites. The spatialization can then follow two alternative ways: data or model-driven. The first one is more suitable for a large number of easy to measure and cheap indicators, representative of the territory. The second way is for precise and sensitive (e.g., biological) indicators, when they are strongly related to one or more covariates of interpolation (e.g., land use).

the investigation at the monitoring sites. In this case, the extrapolation is model-driven, therefore the selection and calibration of the model to spatialize the information are fundamental to obtain reliable soil quality assessment of a certain area.

The selection of monitoring time frames is also fundamental for soil quality assessment because the effect of climate, soil moisture conditions, stage of plant growth, and human factors can cause great temporal variability in indicator status. Biological and biochemical indicators, in particular, show strong temporal variability, mainly due to fluctuations of soil temperature and moisture. The response time for an individual indicator to change, as a result of management, determines the appropriate time interval for monitoring indicator changes.

Indicators with a strong sensitivity to rapid changes (Table 1) may be used as either an “early warning system” of degradation, or to assess the effectiveness of soil management changes at the field scale. Different management practices affect different aspects of soil functionality, especially indicators associated with labile organic carbon, enzymatic activity, and biodiversity. For instance, changes in tillage intensity appear to have greater effects than organic vs. conventional practices (van Es and Karlen, 2019).

It must be also considered that for the soil system many natural or anthropic interventions can be seen as “catastrophic events,” in the sense that they largely disturb and disrupt soil characteristics and functionalities. Exceptional events, like flooding and consequent accumulation of sediment, aeolian erosion and deposition, slumps, earth slides, or gully erosion, can result in truncation of the soil profile or its burial. Similarly, anthropic activities such as land leveling, slope reshaping, and deep ploughing can profoundly modify the soil profile and its quality (Costantini et al., 2018). In these cases, which are increasingly frequent in both space and time, there is little value in considering the sensitivity of soil quality indicators because they might all change abruptly. On the other hand, at the landscape spatial scale, it is critical to consider indicators that focus on long-term changes, to overcome the short-term variation in land use and management. Soil indicators that change slowly are more related to inherent soil qualities and can reflect the impacts of climate and long-term management changes (Pellegrini et al., 2018).

The placement of monitoring sites should reflect the soil spatial and temporal variability of the indicators used. This is perhaps the most delicate and professional part of the work. The areas selected must be representative of both the soil and management practice to be assessed. A more accurate delimitation of the study area within a management type can take place based on the characterization of soil through proximal sensing by, for example, geoelectric, spectrophotometric and radiometric sensors. It is crucial to make comparisons within the same type of soil. The great variety of soil properties, even within a limited territory, means that the values of soil indicators cannot be compared with those at a different soil site. The risk is that of arriving at wrong or approximate evaluations, as a consequence of inadequate sampling. Correct use of the indicators passes from a comparison with the measurements carried out on the same area before starting the testing of the management practice, or on similar and nearby areas that have not received the treatment studied but have the same soil type.

Most common soil quality and health indicators

The main soil indicators can be grouped according to their relevance to provide specific functions. In this chapter, we focus on the soil indicators that are related to soil quality and health, are affected by management, and sensitive to variations. The indicators related to soil functions that are not directly related to soil management, namely the ability of the soil cover to support human activities and infrastructures (bearing capacity) or to be used as a source of raw materials, the role of an archive of geological and archeological heritage, its cultural and esthetic values, are omitted. Among the indicators described below, those that are most relevant and commonly used in monitoring programmes are reported in Table 1.

Water supply

One of the most important soil functions is to provide and regulate the water uptake by plants and other organisms that live in the soil. Soil degradation very often goes together with the impairment of this paramount function. The potential water supply can be assessed and monitored in different ways, but the most common soil indicators are available water capacity, rooting depth and volume, bulk density, and soil salinity.

The most common indicator used to estimate the amount of potentially available soil water for plants is the so-called “available water capacity” (AWC), which refers to the water held in the soil between “field capacity” (matrix potential of fine earth (<2 mm) at -33, -10 kPa for sandy soils) and “permanent wilting point” (matrix potential of -1500 kPa). The easily available water is the fraction of AWC held between -10 and -200 kPa, which is more affected by temporal variation and soil physical conditions, in particular macroporosity and structure. In addition, the study of the relationship between water tension and volume (water retention curve) can provide useful indicators of the soil structural quality. Many times, AWC is estimated through particle size distribution.

The amount of water that is potentially available for plants depends on the soil volume that can be explored by roots. Rooting volume is based on multiple factors. First, rooting depth, the distance between the soil surface and a horizon or layer preventing root penetration, such as a consolidated substrate, a cemented pedogenetic horizon, a layer very rich in salts, or a water table. Second, there is the need to subtract the volume of soil that cannot be penetrated by roots, namely the quantity of unaltered skeleton, very firm clods, and the parts of the soil profile volume that show very marked compaction (Piori et al., 2021).

Soil penetration resistance can be useful for estimating the compaction of soil horizons. It indicates root-impeding layers, such as hardpans or dense soil layers, and can be used to compare relative strengths among similar soil types. Moreover, field observation of soil consistence and root growth pattern can give useful hints on where to place the measurements.

Table 1 Key soil functionality indicators.

<i>Soil indicator</i>	<i>Sensitivity to changes^a</i>	<i>Method of evaluation and analysis</i>	<i>References</i>	<i>Cost of sampling and analysis^b</i>
Available water capacity	Low	Sandbox and pressure-plate extractors	Cassel and Nielsen (1986)	Medium
Rooting depth and volume	Low	Visual assessment, bulk density, penetration resistance	Priori et al. (2021)	Low
Bulk density	Medium	The core method	Arshad et al. (1997)	Low
Penetration resistance	Medium	Penetrometer	Herrick and Jones (2002)	Low
Wet aggregate stability	Medium	Wet sieve procedure	Le Bissonnais (1996)	Medium
Hydraulic conductivity	Medium	Two-ponding head method; disc permeameter; pedotransfer functions	Reynolds et al. (2000)	Medium
Infiltration capacity	Medium	Double ring infiltrometer; disc permeameter	Lowery et al. (1997)	Medium
Crusting susceptibility	Medium	Cone penetrometer; pedotransfer functions	ASAE (1994)	Low
Erodibility	Low	Pedotransfer function	Torri et al. (1997)	Low
Total nitrogen	High	Micro-Kjeldahl determination; dry combustion	FAO-GSP-GLOSOLAN (2021)	Medium
Potentially mineralizable nitrogen	High	Anaerobic incubation	Drinkwater et al. (1997)	Medium
Available phosphorus	Medium	Olsen, Bray, and Mehlich methods using sodium bicarbonate or other extractants	FAO-GSP-GLOSOLAN (2021)	Medium
pH	Low	Electrode system	FAO-GSP-GLOSOLAN (2021)	Low
Cation exchange capacity (CEC)	Low	Sum of cations on the exchange complex	Sikora and Moore (2014)	Medium
Base saturation of the CEC complex	Low	Calculation—percentage of bases on the total exchangeable cations	Sikora and Moore (2014)	Low
Sodicity—Exchangeable Sodium Percentage (ESP) of the CEC	Low	Calculation—percentage of sodium on the total exchangeable cations	Sikora and Moore (2014)	Low
Salinity—Soil Electrical Conductivity (EC)	Medium	Standard electrical conductivity meter system on saturated paste of different soil: water ratios	FAO-GSP-GLOSOLAN (2021)	Low
Total carbonate content	Low	Gas-volumetric method using Dietrich-Fruhling Calcimeter	Sparks (1996)	Medium
Thickness of the Ah horizon	Low	Visual assessment	Jahn et al. (2006)	Low
Organic carbon	Medium	Walkley-Black titration and colorimetric method; dry combustion	FAO-GSP-GLOSOLAN (2021)	Medium
Labile organic carbon	High	Hot-water extractable carbon; particulate organic matter; active carbon	Weil et al. (2003 in Bünemann et al., 2018)	Medium
C:N ratio	Medium	The ratio between organic carbon and total nitrogen		Medium
Microbial biomass carbon	High	Substrate induced respiration (SIR); chloroform fumigation extraction (CFE)	Alef and Nannipieri (1995)	High
Microbial respiration rate	Medium	Laboratory-based soil respiration measurement (static or dynamic)	Bastida et al. (2008 in Bünemann et al., 2018)	High
Enzymatic activity: <i>N</i> -acetyl- β -glucosaminidase, β -glucosidase, butyrate esterase, acid phosphatase, arylsulphatase, β -xylosidase, cellulose and acetate esterase	High	Incubation and fluorescence	Marx et al. (2001)	High
DNA and RNA profiling	High	RNA genes amplified via Polymerase Chain Reaction (PCR), analyzed by Denaturing Gradient Gel Electrophoresis (DGGE)	Kowalchuk (2004)	High
Phospholipid fatty acids	High	Solid-phase extraction and chromatography	Quideau et al. (2016)	High
QBS-ar index	Medium	Berlese–Tullgren extractor	Parisi et al. (2005 in Bünemann et al., 2018)	Medium

^aExcluding intense soil perturbation, such as anthropic earthworks, strong manuring, liming and additions of other materials. High = day and single management variations; medium = seasonal and main year management variations; low = long term variations, land-use changes.

^bHigh = specialistic analysis with skilled personnel and/or high costs; medium = routine wet laboratory analysis; low = low-cost laboratory analysis, field assessment.

Soil bulk density is an indicator of the porosity of the soil mass, therefore of the maximum volume that can be occupied by water and air. It is also called apparent volumetric mass, to differentiate it from the real volumetric mass, or the real density, which depends on the densities of the soil minerals and organic components. It is calculated as the dry weight of the soil divided by its volume, including both the volume of soil particles and the pores. Particular care must be taken to exclude gravels from the computation. Bulk density not only reports the quantity of voids in the soil mass but also reflects the degree of aggregation of the soil particles (the soil structure). Therefore, it is strictly related to the ability of plant roots to penetrate into the soil mass, and also of the soil to function for structural support, water and solute movement, and gas exchanges.

Soil salinity is the accumulation of water-soluble salts in the soil profile, mainly chloride, sulfate, carbonate and bicarbonate of sodium, magnesium, calcium, and potassium. Salinity increases the osmotic potential of the soil water solution, which limits the plant's capacity to absorb water. Salinity can be estimated using electrical conductivity (EC).

Oxygen supply

Most of the organisms living in soil and plant roots need good aeration and the presence of oxygen in the soil atmosphere. Good soil health and functionality go together with a large presence of interconnected macropores, letting the soil atmosphere, which is richer in carbon dioxide, to be oxygenated with atmospheric air. The kind of macropores that ensure an effective diffusion of oxygen within the soil mass are those produced by the biological activity of soil fauna, flora, and roots. The soil indicators used to assess potential oxygen supply are mainly related to soil structure. Apart from wet aggregate stability, particle size, bulk density, and air capacity are among the most utilized. Soil porosity can also be estimated by visual assessment or by the micromorphometric method.

Oxygen supply is also related to sodicity because excess sodium can lead to the destruction of soil structure through the swelling and dispersion of clay particles and the formation of low permeability layers that restrict root growth. Clay dispersion also reduces water infiltration throughout the soil profile and causes waterlogging, clogs drainage pipes, reduces the bearing capacity of the soil (restricting the use of machinery to work the soil), and enhances surface and subsurface soil erosion.

There are also good macro- and micro-morphological methods to assess the state of soil oxygenation. In particular, the field assessment of soil structure and consistence, as well as the study in the field and under the microscope of porosity and redoximorphic features, are considered in the most important soil classification schemes. In the WRB classification system (IUSS Working Group WRB, 2014), in particular, the presence of more or less expressed stagnic properties indicates that the infiltrated water cannot be drained at depth and saturates the soil profile. Gleyic properties, instead, refer to the presence of shallow groundwater for most of the year when soil temperatures permit biological activity.

Nutrient supply

Plants need nutrients in different supply ranges, which are usually higher for productive crops. Among basic macronutrients (nitrogen (N), phosphorus (P), potassium (K), sulfur (S), magnesium (Mg) and calcium (Ca)), total nitrogen and available phosphorus are the most frequently suggested in soil quality and health monitoring schemes (EJP-SOIL, 2021). Plant available phosphorus, in particular, is often the most limiting nutrient for crop and forage production. It is used to monitor chemical soil fertility as it is a stable element, and its mobility in the soil is limited. In addition, potentially mineralizable nitrogen, which represents the fraction of nitrogen that can be easily decomposed by soil microorganisms, is considered in monitoring the effects of soil management on nitrogen availability during the growing season and as an indirect measure of biological activity.

Minor nutrients (molybdenum (Mo), copper (Cu), zinc (Zn), manganese (Mn), iron (Fe), nickel (Ni), boron (Bo), selenium (Se), and chlorine (Cl)), although essential for plant growth, are only considered when symptoms of deficiency in plants have been recognized.

Other main soil indicators of nutrient supply are pH, cation exchange capacity, base saturation, and soil mineralogy. Soil pH gives an important indication of the availability of plant nutrients, and different crops thrive at different pH values. Soil pH may change in response to management activities such as liming, fertilizer addition, irrigation that leads to the accumulation of salts, and some forms of soil pollution. Soil pH controls the solubility and mobility of heavy metals, such as Al (aluminum), Fe, Mn, Cu, and Zn, and nutrients, such as phosphorus. It also controls the toxicity of many heavy metals.

The CEC of soil represents its capacity to hold and exchange positively charged cations, in particular, H, Al, Ca, Mg, K, and Na. The CEC is a characteristic of the soil that is influenced by both very stable (soil mineralogy) and dynamic (organic carbon) properties and affects the soil's retention of fertilizers and other ameliorants. The base saturation of the CEC depends on the presence of Ca, Mg, K, and Na, in contrast to the acidic saturation of H and Al, and it is the basis for cation availability and the buffering capacity of soil pH.

Some indicators highlight the proportion of different cations on the exchange complex (e.g., K/Mg, Ca/Mg). This is particularly important for Na^+ , as an excess of it can negatively alter cell morphology, plant photosynthesis, and chlorophyll production. The exchangeable sodium percentage (ESP) is the amount of Na^+ adsorbed on the surfaces of the soil particle as a proportion of the CEC, while the sodium absorption ratio (SAR) is the relative concentration of Na^+ to Ca^{2+} and Mg^{2+} .

The contents of total and active calcium carbonate are important in regulating the supply of nutrients for plants and microorganisms, and their abundance may decrease the iron uptake, but can also interfere with the supply of water and oxygen. The quantity and activity of carbonates can vary according to soil management, in particular the quality and quantity of irrigation water. Degraded soils may show higher values of carbonates (Costantini et al., 2018).

Regulation of runoff

Soil surface characteristics regulate water runoff and soil in good health can limit runoff by increasing infiltration, while degraded soils on slopes show increased runoff. Soil indicators related to runoff are particle size, surface stoniness, infiltration capacity, and crusting susceptibility. The presence on the surface of gravel and stones acts as a mulch, protecting the surface aggregates from raindrop impact, favoring water infiltration, and reducing runoff. Soil infiltration rate is a measure of how fast water enters the soil under saturated or non-saturated conditions. Water entering too slowly can produce ponding conditions and reflect soil compaction, thus enhancing surface runoff and water erosion. The susceptibility of soil crusting depends on the soil characteristics, such as fine and coarse silt, clay, and organic matter content. Both soil infiltration and crusting susceptibility are strongly influenced by porosity and aggregate stability.

Sediment production

Soil characteristics regulate the production of sediments through erosion. Soil erosion can be caused by wind, water, or anthropogenic activities such as soil tillage. The volume of sediments detached from the soil can be measured in the field with various tools and methods, or by observing visible evidence of soil losses, or can be estimated through laboratory experiments or models that consider soil, climate, morphology, land use and management.

Soils regulate the production of sediments delivered to water bodies through the susceptibility to erosion. The main indicator is soil erodibility. Soil erodibility is the degree of resistance to the impact of raindrops on the soil surface and the shearing action of runoff water. Similar to crusting susceptibility, it can be considered a soil property that depends on soil texture, organic matter content, and aggregation. Other soil indicators related to erosion risk are surface roughness and stoniness, hydrophobicity, but also the content of soluble salts and sodicity in the soil profile, which can cause the formation of erosion tunnels under the soil surface.

Groundwater recharge

An important soil function is the ability to allow the infiltrating water to replenish the groundwater. The process is regulated by the capacity of the soil to infiltrate and hold water and let it percolate throughout the entire profile. Key factors are the depth of groundwater table and the presence of soil horizons that impede vertical movement (e.g., massive clayey layers, thick petrocalcic and petroferic horizons), or create preferential subvertical (e.g., horizons with vertic properties) or subhorizontal flows (e.g., fragic horizons).

The main soil indicators to be considered are infiltration capacity, AWC and hydraulic conductivity of the most limiting horizon of the soil profile.

Purifying capacity and regulation of contaminants

Soils in good condition are an essential filter for clean water and are low in contaminants. Water that moves through the soil is cleaned by physical, chemical, and biological processes. Small pores mechanically filter pollutants and, within pores, the negatively charged soil components, mainly organic matter and clays, capture chemicals with a positive charge, such as many toxic chemicals and ammonium. The bases held on the exchange complex contribute to neutralizing the soil solution, while pH regulates the chemical behavior of toxic elements. Soil organic matter can also have positive charges able to capture some negatively charged chemicals, such as nitrate. Soil bacteria and fungi may transform the pollutants into non-toxic substances such as carbon dioxide and water.

Although the purifying capacity of soil is a complex process, the main indicators used are cation exchange capacity, base saturation, pH, organic matter content, and rooting depth and volume. Indicators of the biodiversity pool are also relevant, but since it is difficult to relate them directly to purifying capacity, they are only used indirectly, or in specific cases of bioremediation.

Any substance that exceeds naturally occurring levels in the soil and poses health risks to life forms, in particular humans, is a contaminant. Soil indicators refer to the presence of contaminants whose nature, location, or quantity produces undesirable effects on the environment or human health. They can be very variable, such as heavy metals, different types of pesticides, excess nutrients, hydrocarbons, microplastics, etc. In Europe, the pollutants most frequently monitored are Cd (cadmium), Co (cobalt), Cr (chromium), Cu, Ni, Pb (lead), Zn, among the potentially toxic elements, while there are organochlorine pesticides, polycyclic aromatic hydrocarbons, and polychlorinated biphenyls, among organic pollutants (EJP-SOIL, 2021).

Carbon sequestration

Soils support vegetation that photosynthetically captures carbon dioxide and host soil organisms responsible for its storage and recycling. Soil organic matter has long been the most widely used quality indicator.

The main source of soil organic matter (SOM) is the above- and below-ground residues of vegetation. The humification and decomposition of these organic materials sustain the soil food chain, as SOM is used as a source of energy for the soil micro- and meso-fauna and fungi. At the same time, mineralization of the plant residues releases nutrients into the soil solution, where they

become accessible for uptake by the vegetation's root system. Soil organic matter is subjected to microbial degradation and its persistence can vary depending on both chemical recalcitrance and physical protection.

The main soil indicator is the organic carbon content, also called the organic carbon density. Derived from it is the carbon stock, which refers to the organic mass of the soil, calculated at the reference depth, considering bulk density and stoniness. Other derived indicators are the temporal changes in organic carbon and/or stock and the stratification throughout the soil profile. The stratification ratio is calculated by the SOC concentration at a shallow depth divided by that at a deeper depth. The stratification ratio is higher in soils that have stored more carbon in the topsoil, whereas it is lower when for example, water or wind erosion has occurred, there is compaction, fertility is poor, carbon input was limited or could not accumulate.

The thickness of the Ah horizon (topsoil mineral horizon with humus accumulation) is another useful indicator to monitor carbon sequestration and the variation in soil health.

Soil organic matter is composed of different functional fractions, which are defined according to their persistence capacity vs. decomposability. There are soil indicators used for monitoring the labile organic carbon fraction or "active" pool, which encompasses only very few per cent of the overall carbon pool and represent the most readily decomposable fraction. Among the most used, there are the hot water extractable carbon (Ghani et al., 2003 in [Bünemann et al., 2018](#)), the particulate organic matter (POM) (Cambardella and Elliott, 1992 in [Bünemann et al., 2018](#)), and the active carbon (Weil et al., 2003 in [Bünemann et al., 2018](#)). The POM, in particular, is the fraction of total organic matter which does not pass through a filter and that typically ranges in size from 0.053 and 2 mm, while active carbon is extracted with dilute, instead of concentrated, potassium permanganate to react with only the most readily oxidizable (active) forms of soil C. The labile organic carbon is responsive to land-use change and management practices, therefore, it has often been considered in monitoring soil health.

Biological activity and cycling of organic matter and nutrients

It is the activity of soil organisms that recycle dead organic matter and mineral inputs, producing mineral forms that plants and microflora can use for vegetative growth, and is at the basis of the soil food web. Several biological indicators have been widely used to monitor soil life in space and time. The most commonly used are the C:N ratio, microbial biomass carbon, microbial respiration rate, and enzymatic activity.

Biological properties are very sensitive to external conditions, as microorganisms require only a brief time to reproduce (from hours to days), allowing them to react to pressure and to transfer genetic modifications swiftly at population levels. This makes these indicators very sensitive to changes, but also increases the relevance of proper sampling. The cycle of organic matter and nutrients is usually evaluated in the laboratory as potential activity, because routine methods for open field measurements have not been standardized (e.g., Tea Bag Index, earthworm test). Potential activity means metabolic activity, including enzymatic activities that soil microbes are capable of developing under optimal laboratory conditions. The decomposition of SOM is carried out by microorganisms through the enzymatic attack of SOM and microbial respiration: extracellular enzymes degrade SOM through hydrolytic or oxidative processes, producing assimilable dissolved organic matter that can be rapidly incorporated by microbes.

Biologically active forms of SOM can function as short-term indicators of longer-term changes in SOM. Autoclaved-citrate extractable protein is an indicator of organically bound nitrogen that is easily mineralized by microbes ([Hurisso et al., 2018](#)).

Biodiversity pool

Healthy soils are capable of hosting great biodiversity. The term "soil biodiversity" is used in a genetic sense and denotes the number of distinct species (richness) in an ecosystem, and their proportional abundance (evenness), but can be extended to encompass phenotypic, functional, structural, or trophic diversity ([Benedetti and Mocali, 2010](#)).

Soil biodiversity plays an important role in supporting the sustainable productivity of ecosystems and regulating multiple other ecosystem services, including nutrient cycling, organic matter decomposition, pollutant degradation, and pathogen control in terrestrial ecosystems. However, the linkages between diverse soil organisms and ecosystem functions remain unclear, and the roles played by bacteria, fungi, protists, and invertebrates for multiple types of ecosystem functions remain largely unresolved. Soil biological diversity reflects the variability among living organisms including microorganisms (e.g., bacteria, fungi, protozoa) and mesofauna (e.g., nematodes, acari, and springtails), as well as the macro-fauna (e.g., earthworms, ants and termites).

Indicators for soil biodiversity include the collection of macro- and meso-organisms in the field by pitfall trapping, their identification and counting by a trained person, following extractions in the laboratory. Regular genomic analysis can also assess biodiversity more accurately at the microbial level. Currently, many methods are available to assess soil microbial diversity. The use of molecular techniques to investigate the microbial diversity of soil communities continues to provide a new understanding of soil properties and quality. Analysis of the soil-extracted nucleic acid sequences (DNA and RNA profiling) provides a powerful tool for characterization of the entire microbial community. The metagenomic approach is another method to assess simultaneously both soil microbial diversity and function ([Benedetti and Mocali, 2010](#)).

The analysis of types and amounts of different phospholipid fatty acids (PLFA) is a biochemical approach that offers an alternative to molecular techniques because it reflects both microbial taxonomic and functional diversity. The amount of total

PLFA can be used as an indicator of viable microbial biomass; further characterization can be done based on the specific signature of biomarker fatty acids (Quideau et al., 2016).

Soil mesofauna composition (microarthropods <2 mm) has been proposed for the evaluation of soil ecosystem services, in particular, biodiversity pools. Soil-dwelling animals play a significant role in the colonization and restoration of degraded biological habitats. Their role includes litter fragmentation, soil aggregation and porosity formation, water infiltration, and the distribution of organic matter in soil horizons. The greater the number of different mesofauna groups adapted to the soil habitat, the better is the soil functionality. Healthy soil systems show a set of ecosystem niches and related organisms, while stressed soils are poorer, both in species and individuals. The QBS-ar index has been developed to overcome difficulties related to identification at the species level, by focusing on the evaluation of adaptability to hypogeal life. Higher values correspond to more complex and soil-adapted communities.

Conclusions

The selection of appropriate indicators for the scope of soil quality and health assessment and monitoring, the methods of analysis, the elaboration and interpretation of results, their reporting and the guidelines given to farmers, policymakers and the general public, are still the object of great debate and a wealth of studies. In general, the list of suggested indicators is never exclusive, leaving room for the use of further indicators. Similarly, the choice of a minimum dataset should have sufficient degrees of freedom to meet the aims of the assessment and the availability of resources. However, the inclusion of at least one or two indicators for each of the physical, chemical, and biological properties of the soil is always recommended to arrive at a proper evaluation of soil functions.

When databases are incomplete for some important soil characteristics, measured data may be substituted by information derived from pedofunctions or rules, based on local, benchmark soils. On the other hand, if the datasets are limited or we make use of many derived characteristics, the benchmark sites are particularly important for validating the results given by the indicators.

The relevance of trained and specific competencies in the use of soil indicators cannot be overemphasized. The selection of indicators and methods of analysis, knowledge of the local soil types and their variability, interpretation and use of the results all require close cooperation of professionals with different and specific expertise.

Future developments should go towards increasing integration between field observations and measurements, use of proximal and remote sensors, and laboratory analysis. It should always be kept in mind that soil is a complex system where processes act throughout the whole profile, not only in the topsoil, and that simplification (use of few indicators or synthetic indicators) and approximations (derivative indicators, pedofunctions) can easily lead to incorrect, incomplete or biased results.

Abstract

Soil erosion is the detachment and transport of slope forming materials by erosive agents. Rates of water-induced soil erosion are determined by interactions between rainfall and runoff, soil type, slope steepness and length, vegetation and land management. As soil is lost through the processes of sheetwash, rill and gully erosion, vital ecosystem goods and services delivered by soils are compromised. The impacts of this justify the use of erosion control measures, which include agronomic methods (the use of vegetation or simulated vegetation); mechanical methods (the use of field engineering structures); and soil management methods (the improvement of soil conditions).

Glossary

Bench terrace A step like landform, designed and built on steep slopes to reduce slope length and erosion risk.

Channel terrace An excavated channel (comprising a cut and fill section) running across slope to intercept any potentially erosive overland flow.

Ecosystem goods and services Ecosystems underpin all human life and activities. The goods and services they provide are vital to sustaining well-being, and to future economic and social development.

Rainfall erosivity The ability of rainfall to cause soil erosion.

Soil erodibility The susceptibility of soil to soil erosion processes.

Soil erosion The detachment and transport of slope forming materials by erosive agents.

Soil loss ratio The relative soil loss under a certain vegetation or land management practice, compared to the soil loss from bare soil that is cultivated up/down slope.

Soil loss tolerance The actual rate of soil erosion at which a deterioration or loss of one or more soil functions does not occur.

Key points

- This chapter defines soil erosion as the detachment and transport of slope forming materials by erosive agents.
- The factors affecting erosion are discussed, namely interactions between rainfall and runoff, soil type, slope steepness and length, vegetation and land management.

- The on-site and off-site consequences (and costs) of erosion are presented.
- The chapter concludes with descriptions of soil erosion control measures, namely agronomic methods (the use of vegetation or simulated vegetation); mechanical methods (the use of field engineering structures); and soil management methods (the improvement of soil conditions).

Nomenclature

t ha⁻¹ yr⁻¹ Metric tonnes per hectare per year

Introduction

Soil erosion is the detachment and transport of slope forming materials by erosive agents, including rainfall, runoff, wind, tillage, and co-extraction on root crops and land-based machinery. This chapter focuses on water-induced erosion of soil on hillslopes. Erosion of river beds, banks and channels, and the movement of slope forming materials solely under gravity (i.e., mass movements).

In natural systems, soil erosion is in balance with soil formation, as an example of ‘dynamic equilibrium’ in the environment. However, land use change, removal of vegetation and soil disturbance by human activities can lead to accelerated rates of soil loss, often exceeding those of soil renewal, which will lead to an unsustainable system. As soil is lost to erosion, the vital ecosystem goods and services delivered by soil resources are also lost. These include production of food, fiber, fodder and biofuels; storage and supply of water resources (helping to mitigate droughts and floods); sequestration and storage of carbon (to regulate our climate); and protection of terrestrial habitats (to support biodiversity) (Adhikari and Hartemink, 2016; Haygarth and Ritz, 2009). Soils have been linked to most of the United Nations Sustainable Development Goals (UN SDGs; (Keesstra et al., 2016)) which drive international governments’ programs and policies in delivering outcomes such as No Poverty (SDG1), Zero Hunger (SDG2), Good Health and Well-being (SDG3), Clean Water (SDG6), Clean Energy (SDG8), Climate Action (SDG13) and Life On Land (SDG15).

Local, regional and global rates of water induced erosion vary over both space and time, and depend on how they were estimated. Measurement and monitoring of soil erosion can be undertaken by field surveys of erosion features such as rills and gullies (Types of water induced erosion), that can be mapped to show the spatial extent of erosion and how this evolves over time (known as ‘sequential erosion surveys’). Field erosion plots, usually covering an area of several m² can be set up to observe erosion processes under natural or simulated rainfall. Catchment-scale studies often involve measurement of sediment loads and concentrations (i.e., eroded soil) in streams and rivers. Remote sensing imagery can measure and monitor soil erosion over large areas, although the resolution of the imagery will tend to capture only large-scale (i.e., >1 m²) erosion features. Finally, soil erosion prediction models have been developed, based on the wealth of observed data on rates of erosion the factors affecting erosion, and also a better understanding of erosion processes. These models are classified as empirical, conceptual, or process-oriented, and predict erosion processes at different spatial and temporal scales. Several of these models are reviewed in Borrelli et al. (2021), including the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978) and the EUROSEM model (Morgan et al., 1998).

The FAO (2019) reports a range of soil erosion rates from 2 to almost 50 t ha⁻¹ year⁻¹. This is compared to rates of soil formation which are estimated to be roughly equivalent to 0.7 t ha⁻¹ year⁻¹ on a global scale (Wakatsuki and Rasyidin, 1992). Tolerable rates of soil erosion, defined as the “actual soil erosion rate at which a deterioration or loss of one or more soil functions does not occur”, range between 0.2 and 2.2 t ha⁻¹ year⁻¹, (Verheijen et al., 2009). The soil loss rates quoted are likely to increase due to (a) expansion of cropland, especially in Sub-Saharan Africa, South America and Southeast Asia (Borrelli et al., 2017) and (b) climate change, where higher intensity, more frequent and longer duration rainfall events are also likely to increase rates of soil erosion (O’Hara et al., 1993).

Processes of water induced soil erosion

The first process of soil erosion occurs when individual or aggregated soil particles are detached from the soil surface by raindrop impacts and or surface overland flow. Detachment occurs when the shear forces of these eroding agents exceed the soil’s resistance to detachment. Thus, the rate of soil detachment is determined by the kinetic energy of the erosive agent (i.e., the mass and velocity of the raindrops and or overland flow) and detachability of the soil (Eq. 1). In the case of rainsplash erosion, the depth of any surface water layer can help protect the soil from the force of the impacting drops.

$$DET = k.KE^a.e^{-b.h} \quad (1)$$

Fig. 1 The cyclical nature of soil erosion processes.

where, DET = detachment of material ($\text{g m}^{-2} \text{s}^{-1}$), k = index of detachability (g l^{-1}), KE = kinetic energy (based on the mass and velocity of the erosive agent) ($\text{J m}^{-2} \text{s}^{-1}$), a, b = experiment coefficients related to soil texture, h = depth (mm) of surface water layer (if any) $KE = 1/2 m v^2$, where m = mass of an object and v = the velocity by which it moves.

The detached material is then transported away, either by raindrop splash (in the jets of water spreading out from the point of raindrop impact) or by overland flow. For rainsplash erosion, the resulting degree of erosion is limited by the small distances covered by the rainsplash jet trajectories. This is usually less than 1 m. On the other hand, overland flow can transport detached particles over much longer distances, depending on the particle size of the material being carried and the kinetic energy, i.e., volume and velocity of the flow. Deposition of transported material occurs when the energy of the erosive agent is insufficient to carry the eroded material. This might be caused by a reduction in the volume of the overland flow (e.g., cessation of rainfall) and or in the velocity of the flow (e.g., friction imparted to the flow). The deposited material may be redetached in the following rainfall event and the whole detachment-transport-deposition process restarts (Fig. 1).

The relationships between soil particle size, flow velocity and energy, and erosion processes are shown in the Hjulström curve (Fig. 2), where soil particle size (x axis) and flow velocity (y axis) will determine whether the particle is detached, transported or deposited.

Fig. 2 The Hjulström Curve, showing the relationship between particle size, flow velocity and erosion process (detachment, transport and deposition).

Consequences of water induced erosion

On-site consequences

Loss of soil depth from erosion has major impacts on soil functions including food production, water regulation, carbon sequestration and storage, biodiversity, and protection of cultural features. Soil erosion reduces the depth and volume of rooting media for vegetation growth. Nutrients, carbon and organic matter held in the soil are preferentially eroded as they are associated with the more erosion-susceptible, finer textured materials (especially silts and very fine sands), making erosion a selective process. Seeds and seedlings can also be washed away with erosion, together with soil biota (flora and fauna), making the remaining 'uneroded' soil less biologically active. This in situ soil also has smaller amounts of nutrients, lower infiltration rates and less water holding capacity, making it more susceptible to further erosion. As a result, a soil profile that has been degraded by erosion is less able to support vegetation cover that may (a) protect it against future erosion events and (b) produce crops to ensure food security (Zhang et al., 2021) (Fig. 3). Soil erosion features can also disrupt field operations and vehicular access to land.

Off-site consequences

Eroded material can be transported by overland flow to the wider hydrological network (Fig. 4). High sediment concentrations in water (turbidity) can affect the aquatic environment in terms of temperature (sediment can absorb more heat than water), oxygen (reduced dissolved O₂ levels) and reduced depth of light penetration. These changes can damage aquatic flora and fauna. For example, sediment can have a significant negative effect on fish populations, as suspended soil particles may damage fish gills and make channel beds unfavorable for spawning (Lazar et al., 2010). Aquatic plant communities can be scoured by soil particles in the flow and smothered by deposited sediments. Water bodies with high sediment concentrations are also unsuitable as sources of irrigation water or sites for hydroelectricity (due to abrasive damage to pipework and turbines). Expensive water treatment to remove sediment can be necessary before it is suitable for domestic or industrial supplies. Recreational activities such as angling, boating and water sports are also impeded by large sediment concentrations in water bodies. Deposited sediment in waterbodies reduces water storage capacities, increasing the risk of flooding during and after high rainfall and runoff events. Deposited sediment also impedes navigation, requiring disruptive and expensive dredging activities to remove the eroded materials.

In addition to these physical and biological effects, eroded soil can be an effective carrier of pollutants and contaminants. Sediments that are easily transported also have the highest chemical adsorption capacity due to their relatively large specific surface area. Agrochemicals such as nitrates, phosphates, herbicides and pesticides can be adsorbed and absorbed onto eroded sediment, and transported throughout the catchment. With the selective nature of erosion, the concentrations of these chemicals can be higher in the eroded sediment than in the in situ soil where they were originally applied. Phosphate is especially associated with eroded sediment, and its concentration in and subsequent release from deposited sediments can lead to eutrophication of waterbodies as excessive nutrient loading encourages algal blooms which deplete oxygen levels for other aquatic species.

Fig. 3 Severe gully erosion on agricultural land in the United Kingdom.

Fig. 4 Poor water quality due to high concentrations of eroded soil from agricultural land, United Kingdom.

The total costs of soil erosion

Putting a financial value on the on-site and off-site consequences of soil erosion is challenging, as many of these impacts cannot be easily monetarized. [Pimentel et al. \(1995\)](#) estimated that the total annual costs of soil erosion by water in the US was \$7.4 billion, which is the equivalent of \$14.4 billion at 2022 prices. Accounting for inflation, the annual costs of soil erosion in England, Scotland and Wales alone were estimated at approximately £285 million at 2022 prices ([Graves et al., 2015](#)). These costs justify the use of soil erosion control measures.

Types of water induced soil erosion

For soil detachment to occur, rainsplash and overland flow must reach a critical shear force to overcome the soil's shear resistance. This can occur at a range of spatial scales, from a few centimeters to several meters. At a very localized scale, 'pedestal erosion' occurs where no overland flow is present, but rainsplash erosion alone preferentially removes soil if there is no surface protection from the raindrop impacts (e.g., bare ground). Rates of soil loss in this case are fairly small ([Morgan, 2005](#)). However, where overland flow is generated (and with sufficient volume, velocity and kinetic energy), then localized flow concentrations (due to surface irregularities caused by roughness elements such as vegetation or stones) can exceed the shear resistance of the soil and detachment by flow will take place. Where there is no obvious eroded channel, this is termed 'wash', 'sheet' or 'interill' erosion. Where flow concentrations do occur, the velocity and kinetic energy of the flow may be sufficient to create small channels or 'rills'. By definition, these erosion features are small enough that they can be removed by the next rainfall event or by conventional agricultural operations, such as plowing ([Fig. 5](#)). However, as these small channels develop, they receive more overland flow, setting up a positive feedback loop which may result in the formation of a 'gully'. These deeply incised, permanent erosion features are associated with very high rates of soil loss and are notoriously difficult to remove. A comparison of different forms of soil erosion and their associated soil losses is given in [Table 1](#).

Factors affecting water induced erosion

There are many factors affecting water induced rates of soil erosion. Many are ubiquitous in time and space because the processes of erosion are universal, even if absolute rates vary. It is important to understand the factors affecting erosion as this can inform the design, use and effectiveness of soil erosion control practices. Many of these factors are inter-related, but here they are discussed independently.

Rainfall erosivity

The potential ability for rainfall to cause erosion is termed 'erosivity'. The raindrops from 1000 mm of rainfall, hitting a hectare of land ($100\text{ m} \times 100\text{ m}$) provide the energy equivalent of 60,000 kcal (250×106 joules) per year. This 60,000 kcal represents about the same energy of 8 L of petrol ([Pimentel and Burgess, 2013](#)). The kinetic energy (KE) available for soil erosion depends on the raindrop mass and drop velocity, which are related: larger drops have higher velocities and hence higher kinetic energies. Raindrop

Fig. 5 Severe rill erosion on an arable field, Herefordshire, United Kingdom.

Table 1 Comparison of different forms of soil erosion.

Form	Mass ^a	Typical velocity ($m\ s^{-1}$)	Kinetic energy ^b	Energy for erosion ^c	Observed sediment transport ^d ($g\ cm^{-1}$)
Raindrops	R	6.0	$18R$	$0.036R$	20
Overland flow	$0.5R$	0.01	$2.5 \times 10^{-5}R$	$7.5 \times 10^{-7}R$	400
Rill flow	$0.5R$	4^e	$4R$	$0.12R$	19,000

^aAssumes rainfall mass of R of which 50 per cent contributes to runoff.

^bBased on $\frac{1}{2}mv^2$.

^cAssumes that 0.2 per cent of the kinetic energy of raindrops and 3 per cent of the kinetic energy of runoff is utilized in erosion.

^dTotals observed in mid-Bedfordshire, England, on an 11 degree slope, on sandy soil, over 900 days. Most of the energy of raindrops contributes to soil particle detachment rather than transport.

^eEstimated using the Manning equation of flow velocity for a rill, 0.3 m wide and 0.2 m deep, on a slope of 11 degree, at bankfull, assuming a roughness coefficient of 0.02. From Morgan RPC (2005) *Soil Erosion and Conservation*, 3rd edn., Blackwells.

size depends on a range of meteorological factors including cloud ambient temperature, air turbulence, particulate concentrations and the weather system (e.g., cold or warm fronts; frontal, convective or relief rainfall). As rainfall intensity increases ($mm\ h^{-1}$), the median drop size (D_{50}) also increases (Laws and Parsons, 1943; Eq. 2).

$$D_{50}\ (mm) = 2.23 * (I/25.4)^{0.182} \quad (2)$$

where I = Intensity ($mm\ h^{-1}$).

Each raindrop falls at its 'terminal velocity' (where it experiences zero acceleration). For example, a raindrop of 1.5 mm diameter falls at a terminal velocity of $5.5\ m\ sec^{-1}$. For a larger 3.0 mm diameter drop, the terminal velocity is $8.0\ m\ sec^{-1}$. Raindrop velocity can be affected by wind, with a reported 3.5-fold increase in rainfall kinetic energy with 'wind driven rainfall' (Helming, 2001; Marzen et al., 2017). The total mass of drops (and their associated terminal velocities) for a rainstorm will indicate that event's erosivity (potential ability to cause erosion).

With the many factors affecting erosivity, simple indices of rainfall erosivity have been devised to quantify the ability of rainfall to cause water-induced erosion. Ideally these indices should be (a) strongly correlated with soil loss and (b) determined from easily available rainfall data. Examples include the 'EI₃₀ index', which is based on the total KE of a storm and the maximum 30-min intensity (Wischmeier and Smith, 1978). It was developed in the US, using data from experimental soil erosion plots. The $KE > 25\ mm\ h^{-1}$ index was devised because the EI₃₀ index was weakly correlated with soil loss in tropical countries (Hudson, 1981). The strongest correlations with rates of soil erosion were given by the sum of the storm KE for all rainfall events with an intensity $> 25\ mm\ h^{-1}$.

Soil erodibility

Soils' susceptibility to erosive agents is termed 'soil erodibility'. It is affected by soil properties such as soil texture, where soils with a large proportion of silt and very fine sand particles are especially susceptible to erosion. This is because larger particle sizes (sands) require more energy to be transported (see Fig. 2), whereas finer textured soils (e.g., clays) tend to adhere to each other, again requiring more energy to overcome these cohesive bonds. Silts and very fine sands lack either of these characteristics. The organic

matter content of the soil is also important as this affects the binding of soil particles and their ability to resist detachment by rainfall and runoff. This resistance to erosive forces is also due to soil chemistry and the attraction of positive and negative ions held on the mineral and organic components of the soil. The chemical interaction of soil particles, minerals and organic matter leads to the formation of polycationic and organo-mineral bridges between particles.

Soil organic matter also improves the soil's water holding capacity, reducing the risk of generating potentially erosive overland flow during or after a storm event. Organic matter also supports soil biology (such as earthworms, fungi, bacteria and plant root exudates) which helps improve soil aggregation and soil structure, stabilizing soil pore networks and connectivity. This facilitates infiltration of rainfall and reduces the risk of overland flow generation. Stable aggregates are also strongly correlated with reduced soil erodibility (Amezket, 1999; Nciizah and Wakindiki, 2015).

External factors such as freeze-thaw, rapid wetting (slaking) and extreme heat (leading to hydrophobic soils) can reduce the aggregation of soil particles, making them more susceptible (erodible) to erosive forces. The way the soil is managed can also affect its erodibility. Field practices such as intensive and repeated cultivations and tillage operations break up stable soil aggregates, making the soil more susceptible to detachment and transport by rainfall and runoff. Removing crop residues after harvest reduces soil organic matter which in turn increases soil erodibility. Large rates of livestock stocking can also remove vegetation, making the soil beneath more susceptible to erosion.

Natural and synthetic soil amendments and conditioners have also been developed to reduce soil erodibility, by making the soil either hydrophilic (reducing overland flow) or hydrophobic (increasing soil resistance to detachment). Products used for runoff and soil erosion control include seaweed extracts, molasses, compost teas and bitumen.

Soil erodibility indices have been derived to generalize and simplify all the relevant factors affecting a soil's susceptibility to erosion. Ideally, these must be (a) correlated with rates of soil erosion and (b) derived from simple and accessible data sets. Examples include the 'K' erodibility index, based on soil texture (silt and very fine sand), organic matter %, permeability and soil structure (Wischmeier and Mannering, 1969).

Slope steepness and slope length

"Obviously, the steeper the slope, the greater the erosion. Not surprisingly, the amount of erosion is not just proportional to the steepness of the slope, but rises rapidly as the slope increases. The length of slope has a similar effect" (Hudson, 1981). As slope length increases, the volume of overland flow accumulates and erosion risk increases because the flow has a greater transporting capacity. The acceleration of that flow also increases on longer slopes, increasing flow velocity and kinetic energy. However, there will be a point at which the flow is carrying too much sediment for its transport capacity and deposition may occur on very long slopes.

An increase in slope gradient (steepness) is associated with higher velocities and kinetic energy of overland flow, which can be expended in soil detachment and transport. Slope gradient has even more effect on flow erosivity than slope length, as expressed in the exponents used in the following equation (Zingg, 1940):

$$E = f(S^{1.4} L^{0.6}) \quad (3)$$

where, E = soil loss ($\text{t ha}^{-1} \text{yr}^{-1}$), S = slope gradient (%), L = slope length (m).

In addition to slope length and steepness, slope profile (cross section) and plan (cross slope) are also important because they determine the concentration or divergence of overland flow. Where landform concentrates overland flow, rates of soil erosion will be higher.

Land use and land cover

The effectiveness of vegetation in controlling soil erosion is best demonstrated when that protective cover is removed, and bare soil is exposed to erosive rainfall and overland flow. Plant traits determine the erosion-control effectiveness of individual plants and vegetation stands. The canopy of the plant will intercept raindrops, so shattering them into smaller drop sizes and reducing their velocity. In turn, this reduces the erosivity of those drops. Plant canopies also reduce the volume of rainfall reaching the ground (where it may generate overland flow), by either evaporation of the rainfall that is intercepted and held on the canopy or by extending the time it takes for the rainfall to reach the ground surface. This reduces the effective intensity of the rainfall and thus its erosivity. Plant stems impart a roughness to surface flow, leading to a reduction in the velocity, kinetic energy and erosivity of the flow, due to frictional effects, turbulence and eddying. Plant stems also absorb some of the flow shear forces that would otherwise apply to the soil surface. The reduction in flow velocity due to the frictional effects of plant stems reduces the transport capacity of the flow, leading to deposition of previously eroded material. Plant stems can also have a physical filtering effect on sediment in the flow, again leading to sediment deposition upslope of the vegetation stand. Plant roots encourage infiltration of rainfall, so reducing the generation of potentially erosive overland flow. Fine roots in the surface soil layer increase soil shear strength (through adhesion and cohesion between the root and soil particles), so reducing soil susceptibility to detachment and soil erodibility. Finally, roots add organic matter to the soil, which is strongly correlated to soil erodibility. More indirectly, vegetation debris provides a protective litter layer on the soil surface, as well as encouraging soil biological activity, and associated aggregate stability and low erodibility (Fig. 6).

Fig. 6 The role of vegetation on soil erosion processes.

The overall effectiveness of vegetation in controlling soil erosion is simply expressed in the 'C' factor of the Universal Soil Loss Equation (Wischmeier and Smith, 1978), where

$$C = C_i + C_{ii} + C_{iii} \quad (4)$$

where, C = effect of vegetation on soil loss and erosion processes, C_i = above ground canopy effects, C_{ii} = at or on ground canopy effects, C_{iii} = residual effects of land use (effects of roots, subsurface stems, effects of soil biological activity, soil structure, organic matter content, soil bulk density, effects of tillage).

In the C factor, the rate of soil erosion under a given vegetation cover is expressed as a 'soil loss ratio' of that under bare soil, all other factors being equal (Table 2). This ratio is determined for the whole cropping cycle, from seedbed preparation to harvest (and management of any crop residues, post-harvest). The original C factors were calculated from observations of soil losses on erosion plots in the US under many different vegetation covers (including unvegetated plots). The C factor for a bare soil is 1, whereas it is 0.001 for a deciduous forest, all other factors being the same (i.e. 0.1% of the soil loss from the bare soil equivalent). While the C factor is a useful device to show the relative effectiveness of vegetation to control erosion, it does not explain the mechanisms by which the different vegetation types (or their components) control soil losses. Soil erosion prediction models such as the modified Morgan, Morgan and Finney model give better expressions of the way vegetation affects the processes of soil detachment and transport (Morgan and Duzant, 2008).

Land management practices

As shown by the 'C' factor above, the choice of land use or crop type will affect the degree of soil surface protection from erosive forces. Arable and horticultural crops (especially row crops) are particularly vulnerable to erosion due to (a) the high degree of soil disturbance during cultivations, especially during seed bed preparation and (b) long periods of bare soil, both post cultivation and post-harvest. Multiple tillage operations will destroy soil structure and soil aggregation, so reducing infiltration and increasing the generation of runoff and soil erosion. Creation of a loose, fine tilth seedbed can lead to surface sealing, impeded infiltration, greater runoff generation and higher rates of erosion. The small soil aggregates created will be highly susceptible to erosion. Soil erodibility is further increased by the loss of soil carbon through oxidation as tillage exposes deeper soil layers to the atmosphere. Soil faunal biomass, including fungal mycelia and earthworms, is important for maintaining cohesive bonds within and between soil aggregates, but soil biology can be adversely effected during soil disturbance.

Reducing the number and or intensity of cultivations preserves soil structural stability and aggregation. Less disturbed aggregates are able to resist erosive forces, as cohesive bonds within the aggregates are maintained. Fewer, less invasive cultivations mean more of the vegetative biomass remains on or within the soil, which can absorb the energy of erosive agents, so reducing erosion rates. For example, a rough, 'trashy' soil surface imparts friction to overland flow, causing turbulence and eddying, resulting in a reduced flow velocity and kinetic energy to erode. Carrying out field operations up and down slope (compared to across slope or on the contour) can concentrate overland flow, so much so that it becomes erosive. Land management practices to control soil erosion are discussed in more detail in the following section below.

Table 2 The cropping ('C') factor for selected land uses/crops (expressed as a ratio of soil erosion under bare soil).

Crop/Land Use	C factor	Crop/Land Use	C factor
Bare soil	1	Millet/sorghum (<i>Sorghum bicolor</i> (L.) Moench)	0.4–0.9
Barley (<i>Hordeum vulgare</i> L.)	0.28	Mulch (e.g., crop residues)	0.025 (100% cover)
Beans (<i>Phaseolus vulgaris</i> L.)	0.2–0.4		0.3 (50% cover)
Cabbage (<i>Brassica oleracea</i> L. <i>Capitata</i> group)	0.6		0.58 (20% cover)
Cashew (<i>Anacardium occidentale</i> L.)	0.4	Oil palm (<i>Elaeis guineensis</i> Jacq.)	0.1–0.3
Cassava (<i>Manihot esculenta</i> Crantz)	0.6	Orange (<i>Citrus × sinensis</i> (L.) Osb.)	0.3
Chilli (<i>Capsicum annuum</i> L.)	0.6	Pasture	0.015
Cocoa (<i>Theobroma cacao</i> L.)	0.1–0.3	Pineapple (<i>Ananas comosus</i> (L.) Merr.)	0.38
Coconut (<i>Cocos nucifera</i> L.)	0.4	Potato (<i>Solanum tuberosum</i> L.)	0.2–0.3
Coffee (<i>Coffea</i> L.)	0.1–0.3	Prairie/savannah grass	0.01–0.10
Corn / maize (<i>Zea mays</i> L.)	0.25	Sorghum (<i>Sorghum bicolor</i> (L.) Moench)	0.65
Cotton (<i>Gossypium arboreum</i> L.)	0.3–0.7	Soybean (<i>Glycine max</i> (L.) Merrill)	0.421
Cultivated grass	0.004–0.01	Sugar beet (<i>Beta vulgaris</i> L.)	0.2–0.3
Deciduous forest	0.001	Sugarcane (<i>Saccharum officinarum</i> L.)	0.4
Disturbed forest	0.04	Sunflower (<i>Helianthus annuus</i> L.)	0.7
Dry evergreen forest	0.019	Sweet potato (<i>Ipomoea batatas</i> (L.) Lam.)	0.6
Floriculture	0.386	Tea (<i>Camellia sinensis</i> (L.) O. Kuntze)	0.1–0.3
Forest/woodland	0.001–0.002 (with undergrowth)	Tomato (<i>Solanum lycopersicum</i> Mill.)	0.6
	0.001–0.004 (no undergrowth)	Vine (<i>Vitis vinifera</i> L.)	0.6
Golf course	0.015	Watermelon (<i>Citrullus lanatus</i> Shrade.)	0.6
Jute (<i>Corchorus olitorius</i> L.)	0.6	Wheat (<i>Triticum aestivum</i> L.)	0.1–0.2 (winter sown)
Mango (<i>Mangifera indica</i> Linn.)	0.15		0.2–0.4 (spring sown)

Soil erosion control measures

Just as human interference can aggravate rates of soil erosion (e.g., by removing vegetation cover), so protective land management practices can be used to reduce soil losses. The control of soil erosion by water (sometimes referred to as 'soil conservation') can be classified into three approaches:

- Agronomic methods: the use of vegetation or simulated vegetation.
- Mechanical methods: the use of field engineering structures.
- Soil management methods: the manipulation of soil conditions.

These methods are inter-related, and in many situations, a single approach is insufficient to control soil erosion on its own and several approaches need to be combined to achieve tolerable erosion rates. Most practices have been developed for agricultural land, but can be applied on other land uses such as construction sites and on engineered slopes (e.g. road and railway embankments and cuttings).

Agronomic methods of soil erosion control

Vegetation is highly effective at controlling soil erosion (Coppin and Richards, 2007). As described above, the canopy, stem, root and litter components of plants interact with soil erosion processes. Agronomic methods of soil erosion control apply these principles in the field. Maximum vegetation cover on the soil surface will protect the soil from erosive raindrops and overland flow, and absorb their kinetic energies. High stem and root densities reduce overland flow volumes, velocities and energy to erode. These effects are achieved through practices such as nurse cropping, high density planting, cover and companion cropping, and crop rotations. Vegetation can be used to reduce slope length and gradient when grown in strips parallel to the contour. The strips may be of different crops (e.g. strip cropping) or as a single vegetative strip across the slope (e.g. field buffer strips). The strips restrict the generation of overland flow and encourage deposition of eroded sediment, so that local slope gradients can be reduced too.

Agroforestry systems grow perennial trees or shrubs together with annual crops. The trees form across-slope barriers to overland flow (also known as 'alley cropping'), so reducing erosion (Nair et al., 1995). The deep tree roots encourage infiltration and reduce overland flow, and leaf fall from the trees adds organic matter to the soil, so reducing its erodibility. Mulches and geotextiles or erosion control blankets (Bhattacharyya et al., 2010) simulate the components of live vegetation that control soil erosion (Fig. 7). By covering the soil, these materials protect it from incoming rainfall and overland flow. When incorporated or buried into the soil, these materials simulate root effects on erosion. Natural-based mulches and geotextiles degrade over time, adding organic matter to the soil, so reducing erodibility. The C factor for soil erosion control geotextiles is estimated at 0.144.

Fig. 7 Nurse crop with a straw mulch (foreground) and coir geotextile (background) for soil erosion control on a new road embankment.

Mechanical methods of soil erosion control

Field engineering structures are used to control erosion on steep slopes, where the erosion risk exceeds the soil loss tolerance.

Terraces

Terraces control soil erosion by reducing slope length and to a lesser extent, slope steepness, so reducing the volume, velocity, and kinetic energy of overland flow to cause soil erosion. There are many different types of erosion control terrace, often developed for local environmental conditions (e.g., the ‘fanya juu’ terraces of eastern Africa; Fig. 8). Other types of terrace include channel and bench terraces. Channel terraces are recommended on slopes no steeper than 7° (12%) (Sheng, 1972). The distance between consecutive terraces down slope can be determined by equations based on site conditions, such as rainfall, soil type and slope gradient. Distances between terrace channels vary as the slope gradient changes, with shorter terrace intervals on steeper slopes. This may cause practical problems for mechanized farming. Channel terraces consist of a dug channel and a filled ridge (constructed from the cut material), excavated across the slope, usually at a gentle gradient of $1:250 = 0.4\%$ slope to carry any overland flow, but at a non-erosive velocity.

Bench terraces are step-like structures, constructed across the slope. They prevent soil erosion by breaking up natural slope lengths into smaller, shorter components, each with a horizontal (or near horizontal) bench and a vertical ‘riser’ (Fig. 9). The dimensions of the benches and risers depend on slope steepness, the desirable width of cultivable land (i.e. bench width) and the acceptable height of the steep wall of the terrace, or ‘riser’ where it remains structurally stable and will not collapse. The construction

Fig. 8 Construction of ‘fanya juu’ terraces for soil and water conservation, Machakos, Kenya.

Fig. 9 Bench terrace, showing height of riser and width of bench.

of the level bench requires the over-steepening of the terrace riser. To prevent collapse of the riser, it must be supported with stones, rocks, masonry, timber or simply a dense network of vegetation roots.

Grass waterways

Field waterways are designed to carry overland flow downslope, at a safe velocity, without causing erosion. These waterways are ideally located in natural depressions to minimize the need to excavate a channel. They are usually lined with dense, short vegetation, stones or geotextiles (Fig. 10). These linings permit high velocity flows without causing erosion. The width, depth and cross sectional area of the waterway are determined by the volume of overland flow they have to carry, the slope gradient and the properties of the channel lining.

Soil management methods of soil erosion control

Farming operations carried out up and down the slope will increase the risk of overland flow generation and soil erosion. Changing to contour cultivations across the slope will reduce these risks significantly. But this is not always practical, especially on complex or steep slopes, where the arrangement of fields on the contour makes field operations such as harvesting difficult and incurs high energy consumption. Contour ridging creates raised ridges across slope, which will reduce localized slope length and effective catchment area for overland flow generation. The ridges can also intercept any overland flow that is generated. Ridges can be joined together at regular intervals by 'ties', so creating small basins, which trap any overland flow and eroded soil, conserving both soil and water within the 'tied ridges' (Fig. 11).

'Conservation tillage' involves the relative reduction of soil disturbance and retention of vegetative material on and within the soil to control soil erosion (Holland, 2004). The term incorporates a continuum of soil management methods including zero/no till, minimum till, mulch tillage, direct drilling, non-inversion tillage, sub-surface mulch tillage and cultivations that combine plowing and planting operations simultaneously (Fig. 12). Conservation tillage aims to maintain soil fertility and control erosion (Cogo et al., 1984). It can also reduce input costs to land managers, as fewer, less invasive cultivations expend less energy and fuel, resulting in considerable rates of adoption in the 1970s in the US during the oil crisis. It should be noted that the success of conservation tillage is related to soil type and timeliness of operations. For example, there is evidence that reducing the number of cultivations can increase bulk density on structureless soils, leading to overland flow generation, which can only be alleviated by deep sub-soiling periodically. Supporters of conservation tillage claim that these are short term effects, which are off-set in the medium to long term by the improvement of soil structure resulting from increased levels of biotic activity and organic matter contents.

Soil conditioners are applied to soils susceptible to erosion. Hydrophilic soil conditioners including tree bark, compost teas, palm oil effluent and seaweed extract often add organic matter to the soil that increases cohesive bonds and the stability of aggregates. The improved soil structure and infiltration capacity reduce the risk of runoff and soil erosion. Hydrophobic soil conditioners including latex, emulsions and molasses, form an impermeable film on the soil surface, which increases the soil's resistance to erosion. The impermeable layer also inhibits infiltration and thus increases the volume of overland flow, but this is unable to detach the soil particles that are bound together by the conditioner.

Fig. 10 Stages of installing a grass waterway for soil erosion control (clockwise from top left: rill erosion in concentrated flow path; marking the width of the waterway; installing a geotextile lining; established grass waterway).

Fig. 11 Tied ridging for soil and water conservation.

Fig. 12 Seedbed conditions: (a) conventional tillage (multiple operations creating a very fine tilth) and (b) conservation tillage (direct drill into previous seasons crop residues).

Gully erosion control

Gullies are erosion features with permanent channels, but intermittent flow. They tend to be deeper than wide. They are notoriously difficult to control, due to their erratic hydrological behavior, high rates of runoff and soil loss, and also they cannot be removed by normal field operations such as plowing. Soil loss is generated at many sites: erosion of the adjacent hillside, and the gully headwall, banks and bed. Prioritizing where soil erosion control measures are needed most can be a challenge, requiring multidisciplinary knowledge of hydraulic and civil engineering, biology, ecology, geology, geomorphology and soil science. The costs of gully reclamation are extremely high, yet difficult to justify in such an eroding and degrading landscape, demonstrating the importance of the principle that “prevention is better than cure”.

Controlling runoff in the gully catchment can reduce the volume of water reaching the gully. Stabilizing the gully banks with wattling, brush layering or stone filled baskets (gabions) can reduce bank collapse and deflect flow away from the gully sides. Check dams (or ‘grade stabilization structures’) are installed in the gully floor to act as an obstruction to flow. This reduces flow velocity and encourages sedimentation upstream of the dam. In time, this deposited material changes the channel gradient and vegetation may establish, retarding flow velocities further. Also, the trapped sediments can store storm runoff. Over time, the pattern of sedimentation behind the dams will create a ‘stepped’ long profile. Check dams can be made of live or dead brush material, rocks (with or without gabions), sandbags, hay bales, timber, sheet steel, masonry, concrete or earth embankments. The spacing of the check dams is given as:

$$S = \frac{He}{K \cdot \tan G \cdot \cos G} \quad (5)$$

where S = Spacing between dams (m), He = Effective dam height (spillway crest to gully floor; m), G = Gully gradient (degrees), K = Constant related to volume of sediment deposited, = 0.3 (if $\tan G < 0.2$), = 0.5 (if $\tan G > 0.2$) (Heede and Mufich, 1974).

Effectiveness of land management measures in controlling soil erosion

The relative effectiveness of some land management practices on rates of soil erosion can be expressed as a ‘soil loss ratio’ (i.e., the ratio of soil loss under a certain land management practice compared to that where no soil control measures are used (Table 3)). Here, the baseline of up and downslope cultivation is given a relative ‘P’ (protection) value of 1. The relative reduction in soil erosion from using different land management practices is then expressed as a ratio of this value.

Conclusion/summary/outlook: A short concluding paragraph

Soil erosion is a natural process, operating in dynamic equilibrium with the processes of soil formation. However, rates of soil erosion can be accelerated by human activities such as removal of protective vegetation, soil disturbance by cultivations and oversteepening of engineered slopes. Soil erosion is exacerbated by climate change (in particular more intense, frequent and erosive rainfall events). Soil erosion and all forms of soil degradation will increase, given the growing demands and pressures put on our finite and limited land resources to supply the world with sufficient food, water and energy, while protecting terrestrial biodiversity. Thus the impacts of soil erosion are felt not only by land managers, but by the whole of society as soil erosion curtails the delivery of many goods and services that originate from soils. Controlling soil losses is vital to maintain these goods and services, but many farmers are often unconvinced about whether erosion control measures will bring benefits (either economic or environmental) to their businesses, either in the short or long term. This suggests that more evidence is needed of the effectiveness of erosion control measures. Also, payments or subsidies are required to encourage uptake of erosion control measures because financial rewards may only accrue in the long term, often beyond the financial planning horizons of many land managers.

Table 3 Relative reduction in soil loss from different land management practices (The 'P' Factor).

Land management practice	P value
Up & down slope cultivation	1.0
Cross slope cultivation	0.75
Contour farming	0.50
Strip cropping, across slope	0.37
Strip cropping, on the contour	0.25
Contouring (on slopes 1–25%)	0.6–0.9 (depending on the slope gradient)
Strip cropping	0.45–0.68 (ditto)
Grass strip 10% cover	0.55–0.65 (ditto)
Grass strip 20% cover	0.50–0.55 (ditto)
Grass strip 30% cover	0.4–0.50
Grass strip 40% cover	0.35–0.40
Grass strip 50% cover	0.30–0.35
Level bench terrace	0.14
Reverse slope bench terrace	0.05
Outward sloping bench terrace	0.35
Level retention bench terrace	0.01

Abstract

Soil erosion by wind is a dynamic physical process, leading to significant soil, air, water, and human health concerns. It occurs as a result of strong winds impacting on loose, dry, bare soils. Although wind erosion occurs on natural landscapes throughout the world, this chapter focuses primarily on wind erosion on cropland and discusses the various impacts of erosion by wind. However, the same principles also apply to natural landscapes. It also examines the processes of wind erosion including the wind profile, modes of particle transport, soil surface conditions, and vegetation as well as modeling, measurements, and control of wind erosion.

Key points

- Wind erosion is the result of the physical interaction of wind forces with the soil.
- Wind erosion impacts not only the soil but also air and water quality as well as human health.
- Wind erosion models help improve understanding of wind erosion processes and control.
- Measurement of wind erosion is needed to design controls, validate models, and assess soil–wind interactions.
- A wide variety of wind erosion control practices have been developed.

Symbols

u_*	Friction velocity (m s^{-1})
$u(z)$	Wind speed at height z (m s^{-1})
z	Height (m)
z_0	Aerodynamic roughness height (m)
u_{*t}	Threshold friction velocity (m s^{-1})
u_t	Minimum wind velocity initiating particle movement (m s^{-1})

Introduction

Wind erosion is a dynamic physical process that occurs when strong winds impact loose, dry, or bare soils. If allowed to continue over time, it can lead to soil degradation. Fine, fertile soil particles are removed during wind erosion (wind-induced particle movement), reducing soil productivity and causing significant on-site and off-site problems. The widespread social and economic hardships that occurred in the United States (U.S.) during the disastrous Dust Bowl days of the 1930s were caused primarily by wind erosion on cropland (Fig. 1). Much progress has been made in reducing the effects of wind erosion in the U.S. through soil conservation efforts made by individual landowners with the technical assistance of the United States Department of Agriculture, Natural Resource Conservation Service (USDA, NRCS). However, wind erosion continues to be an international problem. A recent review of estimates of present-day global dust emissions varied from 500 to about 330 Tg year⁻¹ (Shao et al., 2011). Dust clouds may still be seen in many parts of the U.S. (Fig. 2). Studies by the USDA-NRCS show that wind erosion causes about 7210 million metric tons per year of soil to be lost from U.S. cropland (USDA, 2020). Although significant wind erosion occurs in arid desert

regions and semiarid grasslands, in this chapter we explore the causes, effects, and control of wind erosion on cropland. However, most of the principles of erosion discussed here also apply to natural landscapes.

Global wind erosion was estimated by the United Nations Food and Agriculture Organization (FAO, 2019); they found that North Africa, the border between Iran and Afghanistan, and the Gobi Desert are areas with the highest rates of wind erosion of $>1.0 \text{ t ha}^{-1} \text{ year}^{-1}$. Other areas with less but still severe wind erosion (i.e., $<1.0 \text{ t ha}^{-1} \text{ year}^{-1}$) include the drylands of Iran and Afghanistan, the Arabian Peninsula, as well as dry areas of Argentina, Australia, Chile, Mexico, and the western United States (FAO, 2019). Fig. 3 shows global areas of wind erosion vulnerability based on global climate and soil properties.

Estimates of annual crop loss due to all erosion range from 0.1% to 0.4% that projects a total reduction in productivity of 10.25% by 2050 (FAO and ITPS, 2015). Wind erosion affects crop growth and yield by: (1) removal of the most fertile components of the soil surface (i.e., clays and organic matter), (2) incorporation of subsoil into the surface layer (i.e., degrades soil structure), and (3) a decrease in the rooting depth of the soil including reduced water holding capacity.

Effects of wind erosion

The on-site effects of wind erosion are generally considered to be those in or very near the eroding field, which may be further divided into long-term cumulative effects and immediate effects. The effects of wind erosion on the soil are cumulative and where it is a problem, soil losses often exceed the rates of soil formation dramatically. In extreme situations, wind may erode the entire topsoil horizon and reveal the underlying, less fertile horizons. Wind erosion is a winnowing process that, while it moves all the surface soil in a field, tends to remove the finer, more fertile parts of the soil and transport these materials away from the field. The result is a soil with a lower percentage of silt and clay, lower cation exchange capacity, lower organic matter, and reduced water-holding capacity. All of these factors serve to reduce the productivity of the soil and to diminish crop yields.

Immediate on-site effects of wind erosion also result in economic losses to agriculture. During windstorms, sandblast injury from wind eroding sand grains striking and abrading plants can damage crops, especially seedling stands. Depending on the intensity of the event, seedling stands may be retarded or stunted later in growth and development, damaged to the point that replanting is warranted, or completely destroyed. As the seedlings start to produce true leaves, and especially during exponential growth phases, tissue conversion to woody matter reduces the susceptibility of the plant to damage and the increase in vegetative ground cover tends to reduce wind erosion frequency and intensity. In general, small grain cereal crops are less susceptible to sandblast injury than maize (i.e., corn), soybeans, and sunflowers, which are more tolerant than cotton, cabbage-related crops, and legumes. The least sandblast-injury-tolerant crops are garden vegetables and flowers.

Studies suggest that the off-site impacts from wind erosion may be much larger than the on-site impacts (Pimentel and Burgess, 2013). The estimated off-site costs of wind erosion in the western U.S. range from \$4 to \$12 billion per year (Huszar and Piper, 1986). Off-site impacts from wind erosion are caused primarily by the release of fugitive dust, which may travel long distances and which constitutes most of the airborne dust that settles in homes and on automobiles, imposing costs for cleaning, reduced recreational opportunities, and impaired human and animal health. Estimates of the annual flux of airborne dust deposition over land areas range from less than 10 to about $200 \text{ t km}^{-2} \text{ yr}^{-1}$. As expected, these estimates vary with respect to distance and direction from the major source regions. The source areas of suspended dust are primarily deserts, agricultural operations in arid and semiarid environments, unpaved roads, dry lake beds, braided streams, deltas, and glacial outwash. These areas can be located on any mid-latitude continent, and the literature comprises studies of dust source regions on all continents.

Some suspended dust has been traced across continents, oceans, and around the world (Fig. 4). Significant amounts of suspended dust from Africa are transported across the Atlantic each year, which is deposited in the Caribbean and the U.S. with potential implications for ecological, environmental, and global climate change (Prospero and Lamb, 2003). Fugitive dust obscures visibility and negatively affects air quality. Reduced visibility contributes to the cancelation of airline flights as well as numerous automotive accidents and resulting deaths annually (Van Pelt et al., 2020). Reduced visibility also depresses tourism and recreation revenues. Fugitive dust fouls machinery and adversely impacts environmental health. Pathogens, both plant and animal, may be transported thousands of kilometers on dust particles, even across oceans. Dust from wind erosion has been shown to contribute to global climate change (Prospero and Lamb, 2003) and reductions in snow pack and water supply (Clow et al., 2016). A small fraction of suspended particles may cause health problems when inhaled. These particles are known as PM_{2.5} and PM₁₀, which are particulate matter less than 2.5 and 10 μm in size, respectively.

Wind erosion processes

Soils are susceptible to wind erosion if they are bare of vegetation, exist on extensive or flat areas, lack roughness or aggregation, and are subjected to strong wind forces. Soil erosion by wind occurs when the wind velocity at the soil surface exceeds a critical threshold value, and soil particles detach and move in response to wind shear forces (Tatarko et al., 2019). A soil surface that is rough or protected with non-erodible material, such as vegetation or large stable clods or aggregates, requires a stronger wind to initiate particle movement than a bare, smooth surface.

Wind Erosion Vulnerability

The wind

Wind is simply air in motion, caused by differences in air pressure in the Earth's atmosphere. Since air has mass, when it is moving, it has energy. That energy is what moves soil during wind erosion. Wind erosion is the result of the physical interaction of the wind force on the soil surface. The Earth's surface exerts a drag on the wind, resulting in a vertical profile of wind speed that is described by a semi-logarithmic equation:

$$u(z) = \frac{u^*}{k} \ln \left(\frac{z}{z_0} \right), \quad (1)$$

where $u(z)$ (m s^{-1}) is the wind speed at height z (m); u^* (m s^{-1}) is the friction velocity, which indicates the amount of atmospheric turbulence (its value is independent of height for a given wind profile); k is the von Karman constant (0.4), a dimensionless number; and z_0 (m) is the aerodynamic roughness height, which is a measure of the roughness of the ground surface. From Eq. (1), it is evident that there is a sharp decrease of mean horizontal wind speed as the surface is approached. This gradient in wind speed produces a shearing force caused by surface roughness resulting in a drag on the air flow. The shearing force produces a tangential stress on the surface, called the shear stress, which is equal to the product of the square of the friction velocity and fluid density. The shear stress provides the interchange of momentum necessary for erosion to occur. The susceptibility of a soil to transport due to the effects of wind or water is called soil erodibility. Soil wind erodibility is often assessed using the friction velocity at which particle movement begins, called the threshold friction velocity (u_{*t}). The minimum wind velocity initiating particle movement is known as the threshold velocity (u_t). There is no single threshold velocity but rather a range of velocities, depending on the condition of the soil surface, including plants present, roughness, aggregation, and soil surface moisture.

Particle movement

A soil particle's susceptibility to wind erosion is affected by its size, density, shape, and composition. The quartz sand particle diameter most susceptible to wind erosion is approximately $100 \mu\text{m}$ (Bagnold, 1941). This size of particle begins to move with a wind velocity of approximately 6 m s^{-1} , measured at a height of 2 m. Particles larger than this size require greater wind velocities to initiate movement due to the greater volume and mass of the larger particles. Similarly, particles smaller than $100 \mu\text{m}$ require greater wind velocities to move because of the increased surface area to volume ratios and greater inter-particle bonding forces for the smaller particles. Wind-blown materials erode in three modes of transport known as creep, saltation, and suspension (Fig. 5). Each mode has unique characteristics and effects.

In creep mode (often also called surface creep), soil particles 0.5 to 1 mm in diameter move by rolling or sliding along the soil surface because they are too massive to be lifted into the air. They continue to move until the wind slows, they are stopped by other particles, or they are trapped in a sheltered location, such as a crop furrow or a vegetated area. Creep contributes to loss and deposition within a localized area, filling fence rows and road ditches or burying plants with eroded soil.

Particles between 0.1 and 0.5 mm in size tend to move in saltation (bouncing) mode where they are lifted into the air and accelerated by the wind, returning to surface with greater energy and horizontal momentum, typically within 8 m downwind.

Fig. 5 Soil particles under wind erosion can move in creep, saltation, and suspension mode of transport. Photo credit: USDA-ARS.

Saltating particles return to the soil surface with a force that is a function of their mass and speed, resulting in the disruption of soil aggregates and surface crusts and the release of other particles, thus accelerating the erosion process. Saltation is what causes damage to young plants, threatening their survival. In mature plants, saltation can damage flowering parts and their fruit, reducing their marketability. Like particles under creep, saltating particles continue to move until the wind slows or they are trapped in sheltered areas such as road ditches or streams.

The third mode of particulate transport is suspension, which involves soil particles less than 0.1 mm in diameter. As these fine soil particulates are lifted from the surface, turbulent eddies carry them high into the air. These fine materials may travel great distances in the atmosphere before returning to Earth. Suspension sized particles degrade air quality and cause visibility and health problems. It is this size that includes PM_{2.5} and PM₁₀, both of which are regulated as health hazards by many countries.

For a particle to be lifted to any height, the upward velocity of the eddy must be greater than the terminal velocity of the particle. Sand-sized quartz grains have significantly higher terminal velocities than silt- and clay-sized particles as well as soil particulate organic matter and are rarely lifted to heights greater than a few meters. While in most cases sand-size particles are redeposited in the source field or nearby, in extreme events fine sands may enter true suspension mode and be transported great distances.

As saltating particles are ejected from the surface, they initially rise at an angle of about 25–50° and the force of the wind accelerates them constantly until gravity returns them to the surface. The force these returning particles exerts on the soil surface often results in the ejection of several sand grains from the surface, so the number of grains in saltation often increases exponentially over a short distance of tens of meters in sandy soils. This phenomenon has been called the avalanche effect. There is a limit to the number of grains that can be entrained for any given wind speed, however, the accelerating sand grains exert a drag on the passing wind that results in the transfer of wind energy into the energy of the sand particles and heat of friction. There is thus an equilibrium known as the transport capacity where as much saltating material is being deposited as is being removed from the surface. This is generally not true for particles moving in the suspension mode, as the quantity of suspended particles continues to increase upwards into the atmosphere with increasing fetch across the eroding surface.

Soil surface erodibility

Although wind drives the wind-erosion process, the condition of the soil surface often controls whether or not a soil is transported by the wind. The susceptibility of the soil surface to erosion is called soil erodibility. Any factor that reduces the impact of the wind on the soil surface reduces wind erosion. In addition, conditions that increase the cohesion of particles to produce larger non-erodible aggregates or increase the resistance of particles to detachment from the surface also will reduce wind erosion. For example, intergranular cohesion associated with surface soil moisture increases the threshold velocity needed for particle movement. All of the factors contributing to soil erodibility are the basis for developing control measures, which will be discussed later.

Surface soil texture (the proportions of sand, silt, and clay) is another important factor affecting the erodibility of a site. Sandy soils tend to have weak stability and are easily moved by wind. The USDA-NRCS has related surface soil texture to soil erodibility, classifying the soil into wind erodibility groups according to soil texture and carbonate content (Table 1; USDA-NRCS, 2002). Calcareous soils (soils that contain enough calcium carbonate to effervesce in the presence of dilute hydrochloric acid) tend to be more erodible than similar noncalcareous soils. The surface soil texture and carbonate content are difficult to change and are generally considered intrinsic or static soil properties. However, they may change spatially, over very short distances. Other surface soil properties are temporal in nature and may change annually, seasonally, or even daily. Thus, the effects of these properties on wind erosion may be subject to management practices.

Soil surface roughness, also called microrelief or microtopography, can modify the effect of the wind on the surface, physically protect part of the surface from abrasion caused by blowing particles, and trap particles that may be moving. In tilled soils, tillage tools often create an oriented roughness, or ridges, in the direction of tillage and random roughness due to the random orientation

Table 1 Relation of soil texture to soil erodibility.

Predominant soil texture class of surface layer	Wind erodibility group (WEG)	Soil erodibility index (I) (mg ha ⁻¹ year ⁻¹) ^a
Very fine sand, fine sand, sand, or coarse sand	1	694 ^b 560 493 403 358
Loamy very fine sand, loamy fine sand, loamy sand, loamy coarse sand, or sapric organic soil materials	2	300
Very fine sandy loam, fine sandy loam, sandy loam, or coarse sandy loam	3	193
Clay, silty clay, non-calcareous clay loam, or silty clay loam with more than 35% clay	4	193
Calcareous loam and silt loam or calcareous clay loam and silty clay loam	4 L	193
Non-calcareous loam and silt loam with less than 20% clay, or sandy clay loam, sandy clay, and hemic organic soil materials	5	125
Non-calcareous loam and silt loam with more than 20% clay, or non-calcareous clay loam with less than 35% clay	6	108
Silt, non-calcareous silty clay loam with less than 35% clay, and fibric organic soil material	7	85
Soils not susceptible to wind erosion due to coarse surface fragments or wetness	8	—

^aThe soil erodibility index is based on the relationship of dry soil aggregates greater than 0.84 mm to potential soil erosion.

^bThe "I" factors for WEG 1 vary from 160 for coarse sands to 310 for very fine sands. For coarse sand with gravel, use a low figure. For very fine sand without gravel, use a higher value. When unsure, use an "I" value of 220 as an average figure.

Adapted from the USDA, NRCS (2002) *National Agronomy Manual*. 3rd edn. Title 190 Part 502. Wind Erosion, USDA Natural Resources Conservation Service. Available online at: <https://efotg.sc.egov.usda.gov/>.

of soil aggregates and clods. The effectiveness of tillage-induced roughness on wind erosion depends upon wind direction relative to the orientation of the ridges. Winds in the direction perpendicular to tillage are affected by both ridges and clods while wind in the direction parallel to tillage is only affected by the random roughness.

In agricultural fields, tillage not only creates surface roughness but also disrupts the soil and creates an unconsolidated surface layer of soil aggregates, or clods of various sizes. Some of the aggregates are small enough to be eroded by wind. Aggregates of mineral soils <0.84 mm diameter are generally considered erodible. Larger particles of organic soils are blown because they have much lower density than mineral soils due to the relatively large content of organic material present. The estimated potential wind erosion is related to the amount of nonerodible aggregates, as indicated in Table 2 (USDA-NRCS, 2002). Practices that encourage the development of nonerodible sized aggregates reduce the amount of wind erosion in tilled fields.

The ability of soil aggregates to resist breakdown due to abrasion caused by blowing sand grains or other applied forces is called aggregate stability. Fragile soils have low aggregate stability and are easily disrupted during wind erosion events, causing additional fine material to be added to the wind stream. Aggregate stability is quantified by measuring the degree of aggregate disruption caused by repeated sieving in a rotary sieve or by determining the amount of energy per unit mass needed to crush aggregates of a given size using an aggregate crushing device (Hagen et al., 1995).

Soils often form consolidated surfaces, called crusts, that are more resistant to erosion. Crusts form through physical, chemical, and biological processes. Rainfall often impacts the soil surface with enough force to disrupt aggregates and rearrange the particles

Table 2 Soil erodibility index (I) in units of mg ha⁻¹ as determined by percentage of nonerodible soil, >0.84 mm in size.

Tens ^a	Units (mg ha ⁻¹)									
	0	1	2	3	4	5	6	7	8	9
0	—	694	560	493	437	403	381	358	336	314

^aThe rows and columns represent the amount of nonerodible soil. For example, if nonerodible soil is 25%, first find the 20 in the Tens row and then the 5 in the Units column to find the erodibility index of 193 mg ha⁻¹.

Adapted from the USDA, NRCS (2002) *National Agronomy Manual*. 3rd edn. Title 190 Part 502. Wind Erosion, USDA Natural Resources Conservation Service. Available online at: <https://efotg.sc.egov.usda.gov/>.

on the surface of unconsolidated tilled soils to form a relatively thin physical crust. The crust is denser and more resistant to abrading particles than the unconsolidated soil immediately below it. Very sandy soils form very weak crusts that are easily destroyed by blowing sand particles. However, soils with even a small amount of clay and silt will bind together to form a layer that is 40–70 times as resistant to erosion as entirely erodible soil of the same texture. In rangeland conditions, algae, bacteria, fungi, and other organisms may form biological crusts that are very resistant to wind erosion until disturbed.

In sandy soils, a thin layer of loose, highly erodible sand may form on the surface of a physical crust. This loose sand is very susceptible to the wind and starts to move at relatively low wind speeds. Such loose material will abrade crusts until they fail, typically resulting in a more erodible surface. The amount and distribution of this loose, erodible sand on the soil surface are related to the potential wind erosion of a site. If little or no loose erodible sand is present, erosion generally does not occur.

Vegetation

Vegetation, whether growing, dead, standing, or flat, reduces the susceptibility of the soil surface to erosion. Standing vegetative cover effectively raises the roughness height (z_0) and reduces the shear stress acting on the surface behind the barrier. Standing biomass stems absorb more wind energy than flat vegetative material and are more than twice as effective at reducing wind energy than flat residues. The effectiveness of standing biomass at reducing erosion increases with the height, density, and stiffness of the plants). Modern harvesting equipment such as finger headers on grain combines has resulted in taller grain residue and better wind erosion control. Flat plant residue, while not greatly affecting the value of z_0 , also serves to protect the soil surface from erosion. Dense flat residue and low-growing vegetation effectively shelter the surface against the force of the wind, and thus protect the underlying soil surface. Where the flat residue is less dense, it acts much like random soil roughness elements. If saltation is initiated in a localized area of the field, the saltating grains may strike relatively nonerodible plant material and settle to the ground, effectively stopping avalanching saltation. Where adequate water from rainfall or irrigation is available, winter-cover crops are often planted as a wind-erosion control technique. The adoption of no-till cropping systems throughout the world, most notably in the North American Great Plains, South America, and Australia (Derpsch et al., 2010), has resulted in improved residue management and better control of wind erosion. However, the advent of the biofuel industry and harvesting of crop residues to make ethanol has the potential to reverse this healthy trend. In cropped fields, the crops and resulting crop residues are relatively uniformly distributed. In native plant communities however, the protection afforded by vegetation may be spatially variable. Recent trends in vegetation on some grazing lands are moving away from uniform grasslands toward communities composed of shrubs with bare soil surfaces in between. In such communities, the bare areas tend to form areas of highly erodible soils and the shrubs capture the sediment resulting in nutrient islands and elevated soil surfaces. These isolated elements may funnel wind over the bare areas, resulting in more soil movement. Although the redistribution of soil in such situations is obvious, little is known about net soil erosion in native plant communities.

Wind erosion modeling

Models provide a means to improve knowledge of the many factors that contribute to the processes of wind erosion. In addition, models not only allow users to forecast soil loss given the land condition, they can also be used to evaluate the processes and interactions of climate, land condition, and management on soil loss, without the need for time-consuming and costly field measurements. Several wind erosion models for agricultural as well as natural conditions have been developed over the past decades that vary in degree of complexity and capabilities. A review of many established wind erosion models was provided by Jarrah et al. (2020). These models vary in degree of complexity, temporal and spatial scales simulated, and details of inputs and outputs. A few examples of the more widely used models are discussed below.

The first wind erosion prediction model that was widely adopted in the U.S. was the Wind Erosion Equation (WEQ), developed by the USDA (Woodruff and Siddoway, 1965). The WEQ was developed to predict long-term average annual soil loss from farm fields. The WEQ has been used by the USDA, NRCS to determine soil loss due to wind erosion and to aid producers in designing control practices as well as for various farm programs and the U.S. Natural Resource Inventory (USDA, 2020). The general form of the equation, $E = f(I, K, C, L, V)$, expresses soil loss (E) as functionally related to soil erodibility (I), ridge roughness (K), a climatic index (C), field length (L), and a vegetative factor (V). In practice, the I value is determined from a table similar to Tables 1 or 2 and a series of charts and nomographs are used to apply the other factors in the equation.

The Wind Erosion Prediction System (WEPS) model was developed by the USDA beginning in 1985 and was released to the public in 2010. The overall objective of the WPES project was to take advantage of state-of-the-art wind erosion research and computer technology for improved predictions of wind erosion for conservation planning and wind erosion control (Tatarko et al., 2019). The WEPS is designed to make daily or shorter-time-interval estimates of wind erosion. It is a modular computer-based model that simulates soil erodibility, plant growth, and residue decomposition as affected by weather and field management to predict cropland soil loss at the field scale. The model uses a series of complex submodels that account for the effects of weather, crop growth and decomposition, soil surface properties, soil hydrology, land management, and erosion. In general, the model simulates the weather, grows a specified crop, and determines when erosion occurs based on the soil condition at the time that winds exceed the threshold velocity. Inputs can be as simple as providing the field location (i.e., for weather), the soil present, and a list of management practices applied to the field. The output includes estimates of saltation plus creep and suspended sediment, including PM10 and PM2.5. As a process-based model, WEPS can be used globally with inputs described above without the need for

calibration to a specific location. The WEPS has been applied in studies for Argentina, Burkina Faso, Canada, China, Germany, Kazakhstan, Mexico, and Sweden (Tatarko et al., 2019).

Webb et al. (2006) developed the Australian Land Erodibility Model (AUSLEM). This daily time-step model resulted from a systems analysis of the factors controlling wind erosion. The AUSLEM was developed as a geographic information system tool to assess land susceptibility to wind erosion across western Queensland, Australia. Required inputs include plant cover, soil moisture, soil texture and soil surface roughness. The model was found to perform well in the arid southern and western regions of Queensland.

The Aeolian EROsion (AERO) model was recently developed in the U.S. to assess the impacts of land management and environmental change on rangelands (Edwards et al., 2022). The AERO model uses standardized soil and vegetation monitoring data to develop indicators for wind erosion effects on land health and air quality assessments. The model approach applies a Generalized Likelihood Uncertainty Estimation (GLUE) framework for calibration using vegetation transect, sediment transport (i.e., flux), and meteorological data collected from standardized wind erosion monitoring sites. The model results suggest AERO effectively represents temporal variability in eolian transport.

Concerns about the effects of dust on global climate change has created interest in using models to estimate atmospheric dusts, produced primarily by desert or semiarid ecosystems. Advances in the understanding of atmospheric transport of soil-derived dusts have been made by laboratories in France and Australia. Scientists at the Laboratoire Interuniversitaire des Systèmes Atmosphériques, Creteil, France have developed a dust production model (DPM) considering the size distribution of erodible particles and surface roughness as controls on dust emissions (Alfaro and Gomes, 2001). Scientists with the Commonwealth Scientific and Industrial Research Organization (CSIRO) in Australia have developed a model accounting for the effects of soil, climate, and vegetation to estimate sand drift intensity and dust emission for use at scales ranging from paddocks to regions (Shao et al., 1996). The model known as the Wind Erosion Assessment Model (WEAM), has been coupled with a geographic information system to estimate dust emission over a large area of Australia. Modeling wind erosion in rangelands is a particular challenge due to the complex interaction of vegetation and the wind on the soil surface.

Wind erosion measurement

Measurement of wind erosion is necessary to understand the underlying processes as well as determine the effects of control measures, validate models, and assess the intensity of erosive forces. A wide variety of devices has been developed for this purpose (Webb et al., 2019). Wind erosion assessments typically examine two factors that affect the magnitude of soil loss: (i) erosivity of the climate and (ii) erodibility of the soil surface. Climate erosivity entails standard meteorological measurements for wind, relative humidity, temperature, and precipitation (Webb et al., 2019). Wind velocity is measured as a profile with typically 3 to 6 anemometers positioned at various heights above the surface (Fig. 6). This arrangement is also needed to calculate the aerodynamic roughness height (z_0) of the surface and the wind shear velocity (u^*).

It is important at this point, to distinguish the difference between horizontal soil flux and soil erosion, both of which are reported in erosion research literature. Horizontal soil flux is the mass of sediment passing a vertical plane at a given point on the landscape (e.g., kg m^{-2}). There is usually little knowledge of where on the surrounding landscape the flux began or the surface conditions for which the emissions occurred. Therefore, horizontal flux is typically further used to derive soil erosion, which is the mass loss of soil per unit area of ground surface (e.g., also kg m^{-2}). Horizontal flux can also be used to calculate sediment deposition. Estimates of soil redistribution by wind are often based on the vertical distribution of sediment in transport at multiple spots within a field. If the total sediment in transport at one location is greater than that at an upwind location, net erosion is indicated for the surface interval between the samplers. If the inverse is true, then deposition is indicated for the interval between the samplers. Many types of samplers have been developed to measure the transported sediment at multiple heights above the soil surface and the relative merits of these samplers have been compared (Goossens et al., 2000). The ideal sampler has a high sampling efficiency of collecting sediment without disturbing the wind stream or developing suction or back-pressure. Sampling efficiency for most samplers usually decreases with particle size in the wind stream. Since about 50% of the blowing sediment is transported within 2 cm of the soil's surface, sampling close to the surface is desirable to make accurate estimates of transported material.

A combination creep and saltation sampler was developed by the USDA to sample very near to the soil surface, including creep size, at heights of 0–3, 3–9, and 9–20 mm (Zobeck, 2002). The sampler rotates into the wind and each inlet has a separate collection pan. This sampler is used in combination with other samplers such as Big Spring Number Eight (BSNE) or Modified Wilson and Cooke (MWAC) samplers (discussed below) to analyze the entire saltation zone.

Several types of samplers have been developed to sample the saltation zone, which is about 1–2 m above the soil surface. The BSNE samplers are wedge-shaped samplers with 60-mesh screens on the top or sides to relieve back-pressure and 2-cm-wide and 5-cm-high inlets (Fryrear, 1986). Several BSNE samplers are mounted on a pole to sample at various heights. The samplers have wind vanes to ensure they are oriented into the wind. A similar sampling scheme, the MWAC catchers use bottles mounted on a pole with glass or metal tubes as inlets and outlets (Wilson and Cook, 1980). The larger volume within the bottle allows wind velocities to diminish and eolian sediment to settle within the bottle. This highly versatile and inexpensive sampler may also be modified and mounted to assess the directions from which eolian transport occurs (Fig. 7).

The samplers discussed above are termed passive samplers because they require no external source of power to function. Although these samplers may be used to integrate the sediment transport over periods of time between field visits and sediment

collection, they reveal little about the temporal nature of the sediment transport. For this purpose, saltation impact sensors with piezo-electric elements such as the Sensit or microphone capsules such as the Saltiphone are commonly used (Fig. 8). These sensors allow researchers to determine at what wind speed and z_0 wind erosion begins.

Sampling of the suspended dust load requires more sophisticated instrumentation. Sharratt and Pi (2018) compared the performance of five instruments for measuring suspended PM10 above eroding soils. Optical-based instruments such as the DustTrak are often used in the field to record real-time dust fluxes at a specific height above a point on the landscape. More expensive and larger instruments have also been developed for long-term monitoring of atmospheric dust. The model used by the U.S. Environmental Protection Agency is the Tapered Element Oscillating Microbalance (TEOM). It draws a constant volume of air through a small filter and weighs the filter at predetermined intervals.

While wind erosion measurement devices and samplers give good estimates for a given event or short-term loss, they are rarely employed for periods exceeding weeks or months. Until the last 50 years, there has been no reliable way to estimate long-term rates of wind erosion. However, atmospheric testing of nuclear weapons in the 1950s and 1960s released radioactive isotopes that were distributed worldwide and deposited, primarily by rainfall, on the soil surface. Many of these isotopes, including ^{90}Sr strontium, ^{137}Cs cesium, and $^{239/240}\text{Pu}$ plutonium, are strongly adsorbed to the surfaces of soil clays and organic matter. Strong isotope pulses in 1959 and 1963–64 created a very sharp rise in soil borne radioisotope tracers. Transport of these soil borne tracers is almost exclusively by actual physical movement of the particles to which they are adsorbed. Radioisotope tracers have been used for the last three decades to study the long-term redistribution of wind eroded soil since the radioisotopes were deposited ending in 1964. Radioisotope activity of soil cores sampled at an undisturbed reference site such as native grassland is compared to the activity of soil cores sampled in a field or site for which the long-term estimate of soil redistribution is desired. The loss or gain of radioisotope activity relative to the reference site has been shown to be proportional to the erosion or deposition of soil at the site of interest. Computer models that determine soil redistribution rates from radioisotope activities in different landscapes were developed and validated against, carefully measured wind erosion studies on the U.S. Southern High Plains by Van Pelt et al. (2007).

Wind erosion control

Any control treatment that reduces the wind at the soil surface to below that of the threshold of particle movement, will control wind erosion. A wide variety of practices have been developed, which have been summarized below. The more common control practices for wind erosion are briefly described below.

Vegetation and vegetative residues

The easiest and most cost effective control of wind erosion for most situations is to establish and maintain adequate vegetative ground cover. The value of plant materials to reduce wind erosion has been recognized for several decades. Any practice that keeps live crops or preserves crop residues on the surface after harvest will reduce potential wind erosion (Fig. 9). Live plants and crop residues protect the soil from wind by absorbing a portion of the direct force of the wind, trapping moving soil particles, and promoting aggregation of soil particles. Planting crop rows perpendicular to the prevailing winds is more effective in the control of

Fig. 9 (A) Vegetative wind erosion control includes keeping live plants on the surface and (B) maintaining sufficient residues after harvest. Photo credits: USDA-NRCS.

wind erosion than rows parallel to the wind. In addition, practices that leave vegetation in a standing orientation are more effective in controlling wind erosion than residues that are flat. Reducing excessive tillage (i.e., reduced or no-tillage management) will maintain surface residues and generally reduce wind erosion. Maintaining a soil surface area cover of 30% has been shown to reduce soil erosion to tolerable levels, with only marginal improvements in soil loss prevention achieved with higher percentages of cover (Fryrear, 1985).

Barriers

Wind erosion tends to increase downwind with field distance due to the avalanche effect, therefore, an effective reduction in field length is often accomplished by windbreaks or barriers. Barriers may consist of single rows of trees or shrubs (Fig. 10A) or elaborate windbreaks called shelter belts that have multiple rows of vegetation, including trees and shrubs (Fig. 10B). The use of trees planted in windbreaks or shelter belts to control wind erosion dates back to the U.S. Dust Bowl of the 1930s. The effectiveness of windbreaks depends on their height, porosity, and orientation to prevailing winds. Barriers planted upwind and perpendicular to prevailing winds are more effective than those parallel or downwind of the field. Barriers have been shown to reduce wind speeds for as much as 30 times the height of the barrier (Hagen and Skidmore, 1971). As a general rule however, wind breaks reduce wind erosion for a distance of up to 10 times their height in the downwind direction and three times their height in the upwind direction. Barriers also capture snow, reduce evapotranspiration, improve crop yields, shelter homes and livestock from the wind, and provide fuelwood and wildlife habitat (Cable, 1999). Unfortunately, the number of effective shelter belts has greatly diminished and many have been intentionally removed (Sorenson and Marotz, 1977). More recently, a large-scale tree planting in China was begun with the Three-North Shelterbelt Programme, an effort to establish eventually 4.06 million km² of trees along the border of northern China's encroaching desert by 2050. Similar projects have been attempted across the Sahara Desert in northern Africa in Burkina Faso, Nigeria, and Ethiopia with only limited success (Goffner et al., 2019).

Fig. 11 (A) Perennial grass barriers protect cucumbers in South Carolina and (B) an example of strip cropping in Montana consisting of live wheat alternating with fallow areas. Photo credits: USDA-NRCS.

More recently, annual crops have been used as more closely spaced shelter belts within a field. Spacing of these ‘wind strips’ varies from two rows of wheat planted in the furrows between rows up to 5–10 m-wide strips of vegetation planted at 100–300-m intervals throughout the field (Fig. 11A). Widths of greater than 4.5 m of such herbaceous barriers also trap saltating particles to provide additional protection from the effects of wind erosion. Other advantages of these types of barriers are their ease of establishment and low cost. In emergency situations, other physical barriers such as a snow fence may be used. The recommended porosity of barriers is about 40% for best results (Hagen and Skidmore, 1971; Papesch, 1992).

Strip cropping

Strip cropping involves planting crops in alternating strips of crops susceptible to wind erosion with strips having a cover resistant to wind erosion (Fig. 11B). This practice shortens the field length in the direction of the prevailing wind, thus reducing the avalanche effect and trapping moving particles in strips with cover. Like many practices, the strips should be oriented perpendicular to the prevailing erosive winds. Wheat-fallow systems sometimes use this practice where the fallow strips alternate with growing wheat one year and are interchanged the following year.

Soil aggregation and roughness

In some situations, it is not possible to maintain a vegetative cover on the soil surface due to crop type (e.g., cotton or beans) or management practices (e.g., tillage for weed control). In such circumstances, tillage may be used to maintain suitable soils in a cloddy condition (Fig. 12). The goal is to create soil aggregates large enough to resist the wind force and trap smaller moving

Fig. 12 Tillage in this field produces a rough cloddy condition that is resistant to wind erosion. Photo credit: USDA-ARS.

Fig. 13 Ridges can provide wind erosion control when oriented perpendicular to the prevailing erosive winds. Photo credit: USDA-ARS.

particles. Soil texture is an important factor in creating wind resistant clods. Coarse textured soils such as sands do not have enough clay and silt to bind particles together to form aggregates. Soils with higher clay and silt contents, (e.g., loams, silt loams, clay loams) consolidate to form strong aggregates that are somewhat more resistant to erosive winds and saltating grains. Care must be used to ensure tillage is done when the soil is moist enough to create clods. Tilling dry soils may exacerbate the problem by further pulverizing the soil and creating even more erodible particles.

Ridges and furrows perpendicular to the prevailing erosive wind direction provide improved protection compared to simple random roughness from soil clods. Ridge and furrow systems also trap drifting soils in the lower position of furrows, thus reducing the advance of erosion across a field (Fig. 13). While a cloddy soil surface will absorb more wind energy than a flat, smooth surface, a soil surface that is both ridged and cloddy will absorb even more wind energy. However, roughness can degrade over time as the result of rainfall, freezing and thawing, as well as the wind itself and should not be considered a permanent control.

Chemical treatments

Chemical treatments, such as applying polyacrylamide or plant processing byproducts have also been used to control soil blowing and suppress dust (Movahedan et al., 2012). These chemical treatments bind the surface soil particles together. Any disturbance to the treated areas greatly reduces the effectiveness of the treatment, however. For example, precipitation or saltating soil from adjacent untreated areas that may abrade the treated areas will cause the chemical treatment to fail. Chemical treatments also tend to be expensive and are usually restricted to smaller, high-value crops or areas.

Emergency control

The controls presented so far are designed to be preventative measures. However, once a field actively begins to erode, emergency controls may need to be applied as soon as possible to avoid damage to the soil, crop, and the environment. The various methods of emergency control focus on stopping the process of erosion that is active. Addition of residues, either plant or animal (e.g., manure) have been successfully used to control active wind erosion. Typically plant residues require anchoring with a stubble puncher or disk to prevent the residue from blowing away in strong winds. Another method is emergency tillage, which is done perpendicular to the wind to create a rough, cloddy, or even ridged surface to reduce the wind force and trap moving particles. Implements such as listers, chisels, shovels, and sandfighters are often used for emergency tillage to roughen the soil surface and create clods. This is typically used only when other measures have failed and is considered only a temporary control.

Summary

Scientists at various universities and government agencies throughout the world continue to research the processes, causes, and control of soil erosion by wind, which continues to threaten a sustainable food supply worldwide. This research has the ultimate goal of developing better control strategies for improved management for a sustainable agriculture that protects the soil, air, and water resources. A comprehensive understanding of the principles of wind erosion is needed for developing control strategies. However, extreme weather resulting from climate change can cause drought and shortage of protective vegetation that will exacerbate the problem.

Abstract

Resuspended dust emitted by unpaved roads contains particles that penetrate the respiratory system. When these particles come from contaminated soils, toxins reach the brain or blood circulatory system, generating health disorders. Scientific studies assessing the effect on human health, and the methodologies to determine their roadside transport, together with their physical and chemical characteristics, are presented. Techniques to collect road dust samples due to vehicular and wind erosion are described. Transport models relating vehicular and road wind erosion resuspension and corresponding human exposure are also discussed. Some of the literature results indicate that children and the elderly are at special risk.

Key points

- Road dust, generated by traffic resuspension and wind erosion, affects human health.
- Health effects depend on the chemical composition of the road surface.
- The smaller the particle size of road dust, the more dangerous to human health.
- Children are at special risk from road dust emissions.
- Vehicular resuspension exposure decreases rapidly with increasing distance from the road.

Introduction

Road dust consists of solid particles that are generated by mechanical processing of materials, including crushing, grinding, rapid impact, handling, detonation, and decrepitation of organic and inorganic materials such as rock, ore, and metal (Khan and Strand, 2018). This road dust, or aeroparticles, becomes airborne when local windspeed is above a certain threshold, or by traffic resuspension caused by vehicular aerodynamic wake and shear stresses on the road surface set off by vehicular traction.

While road dust from paved roads contains mainly minerals, brake wear, tire wear and carbonaceous emissions, unpaved road emissions contain the same chemical compounds as those found on the road surface. In general, road aeroparticles emissions are associated with vehicle traffic and road moisture content. Dust emissions from unpaved roads have been found to vary directly with the fraction of silt (particles smaller than 75 μm in diameter) in the road surface materials. Typical silt contents vary according to the type of unpaved road. Industrial unpaved roads contain from 0.2% to 29%, while rural dirt roads with compacted, bladed, and crowned local material have still higher silt contents.

Many communities and regions around the world with predominantly unpaved roads are affected by road-dust. The latest shale oil boom, starting in 2007 in the North Dakota Bakken region, has resulted in a renewed interest by the scientific community in road dust, since many of the oil fields are communicated by dirt and gravel roads. Besides oil, other industrial activities such as mining are major sources of trace elements contained in road-dust, mostly due to waste and emissions during the processing of the extracted materials such as tailings, waste rock deposits and smelting operations (Rodríguez Martín et al., 2014).

Table 1 shows some examples of the chemical compounds found near unpaved roads, depending on the characteristics of the surroundings. Typically, the largest metal concentrations are found in the finest size fractions of the road dust. The partial list of examples in Table 1 point out that the chemical compounds found in road dust depend on the soil composition and industrial activity of the surroundings.

The exploitation of coal, gold, uranium, wolfram/tungsten, tin, platinoids, and polymetallic sulfides cause the most severe cases of soil pollution whenever mining is carried out. Pollution of soil from trace elements at sites surrounding coal mines were reported to be the highest in Barapukuria in Bangladesh, Ledo in India, Ptolemais-Amynteon in Greece, and the Tibagi River in Brazil (Sahoo et al., 2016). Gold mining operations can cause emissions of mercury (Hg), cyanide, arsenic (As), zinc (Zn), lead (Pb), nickel (Ni), and other toxic elements.

During the transfer and transport of ore concentrates to the smelter, spillages are a potential source of road soil pollution. Particulate and gaseous emissions from a smelter that lacks appropriate abatement technologies is a local and distant source of trace elements pollution of soils (FAO and UNEP, 2021).

Many rocks are naturally rich in trace elements, which are mobilized when extracting them from the ore reservoirs. Mining wastes still contain trace elements, but in concentrations at which it is not cost-effective to extract them, but which may still pose a risk to the environment and human health. This is the case of Manganese (Mn) in the mining district of Molango, Hidalgo, Mexico, where the mineral waste contains 18% of Mn (Riojas et al., 2009).

Exposure to air pollution

Exposure refers to a contact between an airborne contaminant with the human skin or the respiratory system. Therefore, exposure requires the simultaneous occurrence of two events: a pollutant concentration at a particular place and time, and the presence of a person at that place and time. Exposure is expressed quantitatively by a description of the duration of the contact and the relevant pollutant concentration. It can be acute if the exposure lasts seconds or minutes, or it can be chronic if it lasts days or months. The accumulation of repeated acute exposures leads to chronic exposure.

Concentration and exposure are different concepts. Concentration is the amount of a substance per volume or mass of air at a certain time and place, whereas exposure describes an interaction between the environment and a subject. Also, there is a distinction between exposure and dose. Dose is the amount of the pollutant that crosses one of the body's boundaries and reaches a target tissue. For example, it can be obtained by dividing the mass or volume of a pollutant by the blood volume.

The size and chemical composition of road dust are the main components to assess its health impact. The size of the particles contained in dust determines where these are allocated in the respiratory system. Particle size is described using the equivalent aerodynamic diameter, D , defined by:

$$D = D_g k \sqrt{\frac{\rho}{\rho_0}},$$

where D_g is the geometric diameter, ρ is the aerosol density, ρ_0 is a reference density (1 g cm^{-3}) and k is the shape factor, equal to 1 in the case of a perfect sphere. Essentially, the aerodynamic diameter of an arbitrary particle is equal to the diameter of a spherical particle with a density of 1 g cm^{-3} , which has the same inertial properties in the aerosol as the particle of interest.

As shown in Fig. 1, a particle whose equivalent aerodynamic diameter is 5–10 μm , or PM_{5-10} , is respirable or inhaled, i.e., it enters the respiratory system. In this overall-used notation, PM stands for *particulate matter*. PM_{1-5} material is allocated in the thoracic region of the lung, whereas PM_1 reaches the alveolar level. Here is where interchange between oxygen and CO_2 takes place, and the pollutant may reach and enter the blood stream.

Besides size, the chemicals contained in the particles in solid or liquid phase determine toxicity. This is measured by the hazard index, HI. The hazard index is defined as “the sum of hazard quotients for substances that affect the same target organ or organ system” (US-EPA, 2021). The hazard quotient is “the ratio of the potential exposure to the substance and the level at which no adverse effects are expected” (US-EPA, 2021). The HI is used to indicate the approximate effects of an agent on an organ system.

Table 1 Chemical compounds reported in road dust near unpaved roads.

<i>Road type</i>	<i>Soil composition</i>	<i>Location</i>	<i>Chemical elements/compounds determined in the road dust</i>	<i>Autors</i>
Petrochemical complex construction site	Not specified	Central Taiwan	• Si (10.3%), Al (4.2%), Ca, Fe, K and organic carbon (13%) in the fine fraction. • In the coarse fraction, Si and Al concentrations increment about 2.5 times.	Wei et al. (1996)
Unpaved roads and trails in 29 military and civilian sites	Different soil types, composition not specified	Western United States	• Si, Ca, Al, Fe and K, concentrations depending on the site	Labban et al. (2004)
Public unpaved road; predominantly clay loam	Sand (19–39%), silt (39–56%), clay (22–26%)	New Mexico State University, United States	• C, O, Al, and Si. To a lesser extent Ca, K, Mg and Fe.	Williams et al. (2008)
Surroundings of power plants, impact from unpaved roads and neighboring cities	Not specified	Upper Silesia, Southern Poland	• Cr, Pb, Mn and Se as main trace elements in PM₁₀. • Around 66–70% of the trace elements were found in the PM_{2.5} fraction, unless for Pb, where it increased to 80%.	Zajusz-Zubek et al. (2018)
Unpaved roads in an abandoned mining site in a desertic area	Not specified	Sonora, México	• Fe (18000–20,000 mg kg⁻¹), Ti (2100–2800 mg kg⁻¹), Mn (850–1100 mg kg⁻¹), Zn (435–470 mg kg⁻¹), Pb (227 mg kg⁻¹), As (33–146 mg kg⁻¹), Sb (21–214 mg kg⁻¹), Cu (22–41 mg kg⁻¹) in the soil of unpaved roads. • Concentrations were approximately twice as much in road dust • Pb, As, Zn concentrations were above allowed limits for active mining waste	Del Rio-Salas et al. (2019)
Unpaved roads in farm fields, sandy loam	Sand (62–90%), silt (5–30%), clay (4–8%)	La Pampa, Argentina	• Glyphosate in PM₁₀ (inside farm fields 382–454 µg kg⁻¹; outside farm fields 39–639 µg kg⁻¹) • Aminomethylphosphonic acid (AMPA) in PM₁₀ (inside farm fields 900–4138 µg kg⁻¹; outside farm fields 98–500 µg kg⁻¹) • Organic matter <1%	Ramirez et al. (2021)

PM_{2.5} and PM₁₀ correspond to particulate matter with less than 2.5 and 10 µm equivalent aerodynamic diameter, respectively.

Fig. 1 Schematic showing particle deposition in the respiratory system, according to their size.

Fig. 2 The USA Environmental Protection Agency 4 step risk assessment process. Based on Khan RK and Strand MA (2018) Road dust and its effect on human health: A literature review. *Epidemiol Health* 40: e2018013. doi: 10.4178/epih.e2018013.

As shown in Fig. 2, exposure and dose response are part of the USA Environmental Protection Agency (EPA) risk assessment process. As such, most studies of wind erosion and traffic resuspension of unpaved roads with contaminated soils deal with the issues described in the assessment process boxes.

Road dust health effects

Although several studies have investigated the geochemical composition of road dust, relatively few scientific studies have assessed the effects of road dust on human health. As of 2018, a summary of the current knowledge of the scientific community on the effects of road dust on human health is presented in the review article by Khan and Strand (2018). Their main findings are summarized below.

The main organs affected by road dust are the respiratory and cardiovascular systems. Diseases related to the respiratory system are chronic obstructive pulmonary disease, asthma, fungal infections, allergies, and carcinomas. The health effects in the cardiovascular system are emergency cardiovascular diseases and increased mortality. Other diseases are low birth weight and non-specific carcinomas.

Among the chemical elements with higher HI often encountered in road dust are Pb, As, platinum group elements, aluminum, vanadium, palladium, and polycyclic aromatic hydrocarbons or PAH. Natural elements such as erionite and offretite were also found in some the studies.

Inhaled and ingested Pb compounds are associated with respiratory tract inflammation and may lead to respiratory tract cancer. Potgieter-Vermaak et al. (2012) found that Pb and chromium (Cr) compounds in road dust were present in human body fluids, indicating exposure risks to road dust. Pb is known to be responsible for deficits in neurobehavioral and cognitive development in childhood. Reports have also found that Pb exposure results in reproductive system dysfunction, and that microcytic anemia results in conditions such as hypertension and chronic renal failure.

Xu et al. (2013) found greater concentrations of As than other components in road dust near industrial and commercial areas. They found a higher HI for children near industrial plants, due to road dust. Additionally, the risk of cancer associated with As exposure via road dust was high in children. As has both carcinogenic and non-carcinogenic effects on humans. In a meta-analysis, As was found to be associated with cardiovascular disease, birth defects, neurologic and cognitive disorders, diabetes, ototoxicity, peripheral vascular diseases, and disorders of blood cells such as anemia and leukopenia (Tchounwou et al., 2003). This review also found an association between higher levels of As exposure and carcinomas of the skin, liver, lungs, kidney, colon, and urinary bladder.

Colombo et al. (2008) established an association between respiratory tract diseases and platinum-group elements in road dust. They reported that the bioavailability of the platinum-group elements depended on their concentration in road dust. Platinum (Pt) was found to have higher bioavailability in human gastric fluid than palladium (Pd) or rhodium. Zereini et al. (2021) found a higher concentration of platinum-group elements in PM₁₀ road dust and found that Pd had a greater concentration than Pt or rhodium. They reported that Pd was more soluble than other platinum-group elements, thus causing a potential health risk to humans. Transport activities due to manganese mining that are harmful to health are reported in Riojas et al. (2009), Jazcilevich et al. (2012) and Cortez-Lugo et al. (2018).

Long-term exposure to aluminum (Al) was found to be associated with Alzheimer's disease. Aluminum was found to be associated with respiratory allergies, such as asthma, in aluminum industry workers. The accumulation of Al can cause cardiac hypertrophy leading to cardiac failure. Al deposition in the body was found to cause inflammation in the hepatobiliary system, and to be associated with anemia and a low reproductive rate in rats.

Jiang et al. (2014) found high levels of PAHs in road dust. They estimated that the risk of cancer from PAH in road dust was higher through the dermal and ingestion routes than through inhalation. They found that children were more susceptible to the hazard than adults, due to their greater engagement in hand-to-mouth activities outdoors and smaller body weight.

Although inhalation is cited as a main route of exposure, ingestion and skin exposure to pollutants are also important. A vulnerable population often appearing in dust road pollution literature are children. For example, Mar et al. (2008), found a strong association between respiratory symptoms in children and PM_{2.5}.

Road dust emissions

The resuspension and wind erosion phenomena affect health because they entail high particulate matter concentrations reaching values in the mg m⁻³ scale, and since the emissions take place in near proximity of humans and their property. It should be clear that the phenomena described here involve scales of less than 150 m. These are appropriate scales to study contaminated soils affecting contiguous communities. The field of long distance transcontinental or regional erosion transport phenomena is not discussed here.

Road traffic resuspension emissions

A central factor of unpaved road aeroparticles is that particle resuspension concentrations are orders of magnitude higher than PM tailpipe emissions: if exhaust PM concentrations are measured in µg m⁻³, atmospheric concentrations emanating from dirt roads can reach the order of mg m⁻³ for short distances and periods of time. If the resuspended dust contains toxic material, its health effects can become acute, and their accumulation may lead to severe health effects.

Since PM tailpipe emissions have been substantially reduced by new internal combustion and aftertreatment technologies, resuspension emissions measurement has become more relevant. Moreover, with the advent of electric cars, resuspension is becoming a main emission source, together with brake and tire wear. Therefore, the main effort in the scientific community has been to develop techniques to evaluate resuspension emission factors for the purpose of building emission inventories for regulatory purposes. The aim has been to obtain how much mass per km is resuspended by a vehicle, and not necessarily to measure corresponding roadside concentrations pertinent to exposure studies. Nevertheless, some of the techniques used in the field of resuspension emissions measurement can be used for the purposes of roadside exposure, since they provide chemical and size distributions.

Mitigation methods for dust resuspension on unpaved roads include paving, speed control and chemical stabilization. Cortez-Lugo et al. (2018) present a case where road paving was used to decrease the amount of resuspended Mn in a mining community. Another frequently used and cheap stabilization measure is the use of dust suppressants, which can reduce PM₁₀ emissions by a factor of 5–60 (Fitz and Bumiller, 2021).

Road wind erosion

Soil erosion corresponds to the removal of detached material from the surface soil and subsequent short transport of particles. It is primarily originated by water and wind. The most important transport mechanism in wind erosion of soils is saltation, where particles (0.1–0.5 mm) fall to the ground and transfer their momentum to other soil particles in a series of short bounces along the surface of the ground, detaching and mobilizing them into the air (Avecilla et al., 2015).

The abrasion of a surface is related to the diameter of the saltating particles, which determines the kinetic energy of each impact. Larger particles manage to suspend particles with smaller sizes in the air. This is especially important in polluted soils, as toxic

compounds can be transported to the atmosphere by this mechanism. As unpaved roads generally contain locally selected and stabilized soils, they can be a major source of airborne pollutants if they are covered with toxic materials, for example, in localities near ore extraction sites, as mentioned in the introduction.

Roadside sampling methodologies

A compendium of roadside resuspension emission techniques can be found in [Casotti and Alves \(2021\)](#). The main findings are presented below. There is no clear agreement on which methodology is more appropriate to perform a road dust sampling campaign. Choices vary from basic sweeping tools to sophisticated devices, as will be shown.

Manual sweeping and vacuum cleaning

In most cases, a procedure to collect road dust accumulated on the surface is done with a dustpan and a brush. Also, vacuum cleaners are used, although the possibility of an incomplete collection exists if no wet brushing is deployed afterwards. These techniques imply a degree of uncertainty since they are not operator independent.

Care must be taken when the samples arrive to the laboratory. For example, the removal of large debris and other undesired objects must be sieved. Then, desired size fractioning is performed in 3–6 size intervals as, for example: <38 µm, <50 µm, <63 µm, <100 µm and even <250 µm. Also, after the sieving process, the finest fraction can be resuspended in a mixing chamber to simulate real world conditions.

Direct sampling

Different research teams hone their procedures according to the local conditions. For example, in Scandinavian countries it is necessary to identify and attribute sources of particulate matter which operate in late winter and spring, such as winter tire equipment and antiskid road treatments ([Gustafsson et al., 2019](#)). This is when accumulated residues from tire and road wear attain higher values and the resuspension process make them reach the respirable fraction of particulate matter. The direct techniques described in [Casotti and Alves \(2021\)](#) are:

Wet dust sampler (WDS)

This device of the Swedish National Road and Transport Research Institute (VTI) is equipped with a spray nozzle that thoroughly cleans the surface ([Gustafsson et al., 2019](#)). It employs high-pressure water to clean small circular road surface areas, and compressed air to move the sample from the washing unit to a sample bottle. The WDS has been used in several Swedish national research projects, mainly for investigating the influence of road operation measures on dust emissions. Models of the WDS can estimate the contribution to PM₁₀ from road dust and other non-exhaust particles. The content of the bottles can then be used to obtain size distribution by laser granulometry.

Testing re-entrained aerosol kinetic emissions from roads (TRAKER) and EMMA

The TRAKER consists of laser photometer instruments mounted on a vehicle, measuring PM concentrations in real time. One set of photometers is installed behind the front tires of the vehicle and measures the resuspended particles. Another set is deployed usually ahead of the front bumper, to obtain background concentrations. Road dust concentrations of PM₁₀ and PM_{2.5} are calculated as the difference between the values obtained close to the tire and the respective background ([Kuhns et al., 2003](#)) via:

$$T = T_T - T_B$$

where T is the signal with background correction, expressed in mg m⁻³, T_T is the PM concentration behind the tire, and T_B is the background concentration in front of the bumper.

A modified version of TRAKER, called EMMA, was proposed by [Hussein et al. \(2008\)](#). This device was used to carry out an extensive sampling campaign over 300 km of the Stockholm area in Sweden, from late spring until autumn 2006.

SNIFFER

Similar to the previous methodology, the mobile laboratory SNIFFER was developed and tested on 20 km of road in Helsinki, Finland, to measure traffic exhaust emissions under real driving conditions from a moving vehicle. It was further adapted for non-exhaust particles ([Pirjola et al., 2004](#)). It consists of two different inlets, one located above the windshield at 2.4 m above the ground, and the other above the bumper, located behind the left rear tire, at 0.7 m from the road surface; see [Fig. 3](#).

EMMA and SNIFFER differ in the sampling inlet location (front tires versus rear tires) and inlet air flow, and the instrument deployed for particle measurements: the optical properties of a DustTrak (a light-scattering laser photometer to measure aerosol mass) versus the gravimetric principles of the TEOM (tapered element oscillating microbalance). Measurements show, in both cases, a positive correlation between concentrations and vehicle speed, but PM₁₀ levels measured by SNIFFER are higher than those collected by EMMA.

"Sniffer"—A novel tool for chasing vehicles and measuring traffic pollutants. *Atmospheric Environment* **38**(22): 3625–3635. doi: 10.1016/j.atmosenv.2004.03.047.

System for the continuous aerosol measurement of particulate emissions from roads (SCAMPER)

TRAKER and SNIFFER focus on tire-road interactions, and they might be disregarding the resuspension of particles provoked by the vehicular aerodynamic wake turbulence. Therefore, [Fitz and Bufalino \(2002\)](#) proposed SCAMPER, a method with the aim of incorporating resuspension mechanisms and directly estimating emission factors. As in the other mobile laboratories, SCAMPER relies on a vehicle on which special equipment is installed and a trailer. PM₁₀ concentrations are measured through three laser-optical instruments: one, on the vehicle roof (background), and two on the trailer. To sample in the trailer only the resuspended particles of the wake, the exhaust gasses are by-passed, and contamination is avoided. Experiments included measurements in a motorway around Aachen (Germany) at a speed up to 100 km h⁻¹.

Online resuspension chamber

[Jancsek-Turóczy et al. \(2013\)](#) designed a mobile sampler for resuspended dust, consisting of a stainless-steel hood placed on a mobile platform to collect road dust. For this purpose, the hood is connected to a leaf blower which simulates the effects of turbulence generated by traffic or wind on road surfaces. The resuspended particles are collected in a cyclone separator that measures the PM₁–PM₁₀ resuspended dust fractions, while PM₁ samples are collected on a filter. The design of the collection method was not intended to be quantitative but can provide the proportion of the PM₁ and PM_{1–10} fractions in resuspended dust.

Different authors have presented variations to the online resuspension chamber to increase accuracy, reduce material loss and to be able to adjust the sampling area. This type of device is mainly used to compare dust loadings over different pavement materials in the dry season, and in different geo-morphological and wind conditions.

Portable in situ wind erosion laboratory

A direct sampling method with the added advantage of determining the potential for wind erosion and dust emission from soil surfaces is the Portable In-Situ Wind Erosion Lab (PI-SWERL; [Etyemezian et al., 2007](#)). This device uses an annular ring that rotates directly above the soil test surface. Dust and sand are mobilized by the shear created by the rotating ring. Dust concentrations within the chamber that encloses the annular ring are measured by light scattering. The PI-SWERL provides a robust index of wind erosion or dust emission potential. Compared to traditional field wind tunnels used for the same purpose, the PI-SWERL offers significant economy in size, portability, and ease of use.

Vertical profile

Most methodologies presented so far involve the collection of road dust directly from the surface, either in dry or wet conditions. To obtain vertical profiles of PM concentrations, canisters are placed on a roadside location. As shown in [Fig. 4](#), the system consists of 6-cm high, and 7-cm wide cylindrical canisters placed vertically. The theoretical assumptions are essentially that particles descend towards the ground with a rate influenced by their deposition velocity and particles rise upwards induced by turbulent eddies ([Amato et al., 2012](#)).

Fig. 4 Vertical profile method. Schematic of sampler array displayed on the roadside. Based on Casotti RI and Alves CA (2021) Road dust resuspension: A review. *Atmospheric Research* **261**: 105740. doi: 10.1016/j.atmosres.2021.105740.

Fig. 5 In (a), electro mechanically controlled device instrumented with $PM_{2.5}$ laser-optical sensors (PDR1500) deployed on a roadside. In (b), corresponding integrated $PM_{2.5}$ concentrations on a 2×2 m orthogonal plane.

Active concentration profilers

The methodologies presented by Casotti and Alves (2021) were not developed with the aim of estimating exposure. As stated in the introduction, exposure requires pollutant concentration and human presence at the same time. Recently, devices have been proposed to obtain near-road concentration fields where pedestrians interact with the pollution. In this way, potential exposure levels are possible to obtain. An electromechanical device continuously samples and localizes roadside atmospheric concentrations on a $2 \text{ m} \times 2 \text{ m}$ plane orthogonal to the road (Jazcilevich et al., 2019). The technique discriminates background from immediate emissions but does not distinguish between resuspension and tailpipe emissions. Nevertheless, if the device were applied in a road-dust setting, where PM resuspension emissions are orders of magnitude greater than tailpipe emissions, it could yield resuspension exposure information. In the limited number of experiments using this device on paved roads, emitted $PM_{2.5}$ concentrations were located at preferred heights on the roadside. These heights are dictated in part by vehicular aerodynamics, and some coincide with children's height. Results also showed that exposure decreases rapidly with increasing distance from the road. The device and an example result are shown in Fig. 5.

Based on Riojas H, Rodríguez S, Hernández D, Cortez M, Shilmann A, Santibañez R, Sabido E, Rodríguez Y, Solís R, Montes S, Ríos C, Mondragón A, Rosas I, Siebe C, Shimada K, Jazcilevich A, Wellens A, Paz F and Catalán M (2009) *Exposición a manganese de la población residente en un distrito minero (México) – fase II. Informe Final. Donación 103052-001. Proyecto conjunto INSP, INNN, PUMA, IG, CCA.*

Emission factors for road wind erosion

Wind erosion PM emissions factors of unpaved roads can be obtained by wind tunnel studies, or the PI-SWRL device. Results vary since emission factors depend heavily on physical soil characteristics. Jia et al. (2013) mention 8 m/s as a threshold wind speed for soil erosion to take place, while Díaz-Nigenda et al. (2018) observed wind erosion emissions with wind speeds over 6 and 9 m/s respectively in two cities in southern Mexico. However, other wind tunnel experiments show that for a windspeed of 3 ms⁻¹ a wind erosion emission factor of 0.0276 mg m⁻² s⁻¹ can be determined over an unpaved road (Riojas et al., 2009).

The emission factors as a function of wind speed obtained in wind tunnel experiments can be used in Gaussian air dispersion models, to simulate a point or line emission. An example of the output of such modeling technique is shown in Fig. 6 for a Mn mining community in central Mexico (Riojas et al., 2009). This study obtained PM_{2.5} and Mn concentrations using AERMOD, considering the unpaved roads as a sequence of sources where emissions were proportional to the road area. AERMOD is a steady-state Gaussian plume dispersion model aimed at short-range (<50 km) air pollution dispersion from point, line, area and volume sources (Cimorelli et al., 2003). Since gaussian dispersion models are based on the solution of the advection-diffusion equation, mass conservation is assured. Therefore, they give a better estimate of how dust concentrations decrease with distance than when using average, linear or exponential attenuation factors.

In Fig. 6, the area most affected by Mn due to wind erosion from dirt roads is shown. The PM_{2.5} emission factors for unpaved roads were obtained in a wind tunnel as a function of surface wind speed from road surface samples. Mn emission factors were adjusted from PM_{2.5} emission factors by determining the Mn content in PM_{2.5} by means of chemical analysis of the soil samples. Modeling results indicated that the effect of wind erosion is local: Mn and PM_{2.5} concentrations increase in areas where several unpaved roads converge. Simulated average Mn concentrations were two to three times above the reference concentration for inhalation exposure, corresponding to 0.05 µg/m³ (US-EPA, 1993). The extension of the area where the reference concentration is exceeded under typical meteorological conditions for the studied community was found to be around 1.2 × 1.3 km².

Wind erosion control can be achieved by two means: reducing wind speed at ground level and increasing soil cohesion, thus improving soil resistance to wind (Duniway et al., 2019). To reduce surface wind speed, green fences can be planted as windbreaks between homes and unpaved roads. To increase soil cohesion, it is highly recommended to pave the roads in rural areas where minerals or other polluting compounds are exploited, especially when these roads are frequently used and cross communities.

From dust to dose

Since exposure relates the pollutant concentrations that come in contact with the human body, we consider it an appropriate name for the material discussed below.

Fig. 7 Typical resuspension $PM_{2.5}$ wave form showing a primary followed by secondary waves. From Jazcilevich A, Wellens A, Siebe C, Rosas I, Bornstein RD and Riojas-Rodríguez H (2012) Application of a stochastic vehicular wake erosion model to determine $PM_{2.5}$ exposure. *Aeolian Research* 4: 31–37. doi: 10.1016/j.aeolia.2011.11.002.

Soil erosion, caused by either traffic resuspension or wind, results in accelerated transport of hazardous materials. This is of particular concern because of potential increased inhalation exposure over a short time. Nevertheless, studies regarding the ensuing mechanisms responsible for this phenomenon are lacking.

The study of exposure to roadside pollution in rural unpaved roads provides a chance to observe isolated events with large concentrations, thus acting as a research magnifying glass providing information about the fluid mechanics in which exposure takes place. For example, in Jazcilevich et al. (2012), it was possible to observe typical shapes of the resuspension of a $PM_{2.5}$ concentration signal generated by a truck traveling on an unpaved road, as shown in Fig. 7. Note that the exposure scale shown is in the range of $mg\ m^{-3}$, several orders of magnitude above the prescribed 1, 8 or 24 h averaged PM health norms, which are given in $\mu g\ m^{-3}$.

To obtain potential inhaled mass, the constraint in short time scales requires appropriate analytical methods for those scales. In the case of Jazcilevich et al. (2012), no time averaging techniques were used since they smear maxima exposure levels. This can reduce maxima by an order of magnitude. Accumulative acute effects can thus be severely underestimated. Also, by using a stochastic model, the turbulent character of the phenomena was preserved. It allowed the estimation of real-life inhaled mass by a pedestrian.

The stochastic model is shown in Fig. 8. The lognormal probability distribution (pdf) was obtained by observing the repeated resuspension signal of a truck passing in front of the instruments under calm wind conditions. The lognormal pdf was tested using Kolmogorov-Smirnov and Anderson-Darling test statistical techniques (Stephens, 1974). To project this information to other near road distances and heights, a function, whose independent variables are height, z , and distance to the road, x , was built. It was obtained by collecting and measuring the weight of resuspended dust mass in vertically and horizontally placed sampling devices at varying distances. The scheme used for this task is reminiscent of the vertical scheme described in Fig. 4, but a set of recipients were added in the horizontal, orthogonal to the road. A function whose independent variables were height and distance to the road was thus obtained. By appropriately normalizing this function, an attenuation factor function $f(x, z)$ was applied to the pointwise $PM_{2.5}$ measurements to project them to the desired distance and height. The stochastic model was tested using a “witness” sensor. A version of the model for the dry-warm and dry-cold season was obtained to account for the corresponding sensible soil heat fluxes variations. Dry-warm conditions resulted in much higher exposure levels.

By repeating the stochastic experiment at desired heights and distances to the road, potential inhaled $PM_{2.5}$ with 15% Mn was obtained for different populations. Results for the dry-warm season are shown in Fig. 9. The number of daily trucks passing in front of an individual was 8, and distance to the road 50 cm. The inhalation rate was calculated as a function of activity, using data from Gratt (1996).

To obtain dosage, the inhaled mass shown in Fig. 9 must be divided by blood or target organ volume. This volume is a function of gender and age. It can be seen that in light to moderate activity, children receive a higher dosage of Mn than adults.

Final considerations

Exposure to road dust resuspension from unpaved roads demands information on composition and spatial concentration fields that come in contact with the human body. The scientific community is advancing technological schemes to acquire resuspension data mainly to obtain emissions factors, i.e., vehicular emitted resuspension mass per km. Measurement techniques to obtain spatial information on road dust, where pedestrian activity takes place, is not being pursued with the same energy. The vertical scheme described Fig. 4, in conjunction with the attenuation function $f(x, z)$ described in Fig. 8, can be implemented to obtain distance-to-the-road concentrations and obtain spatial pollutant fields. This scheme obtains potential acute exposure. Active profilers placed on the roadside as shown in Fig. 5, obtain spatial data to estimate pedestrian exposure.

Since roadside exposure intake is directly related to inhalation rate, analysis must be done in time scales of seconds, thus including information on turbulent phenomena. Otherwise, average smearing leads to severe underestimation of inhaled

Fig. 8 Schematics of the stochastic exposure model. A realization is initiated by generating a uniform random number in the ordinate of the lognormal pdf, as indicated by arrow 1. This selects a concentration, which is multiplied by an attenuation factor $f(x, z)$ to appropriately localize the concentration at a selected height, z , and distance x to the road, as indicated by arrow 2. Based on Jazcilevich A, Wellens A, Siebe C, Rosas I, Bornstein RD and Riojas-Rodríguez H (2012) Application of a stochastic vehicular wake erosion model to determine PM_{2.5} exposure. *Aeolian Research* 4: 31–37. doi: 10.1016/j.aeolia.2011.11.002.

Fig. 9 Respiratory intake of Mn ($\mu\text{g day}^{-1}$) calculated by the stochastic model for eight truck passes at a distance of 50 cm to the road, as a function of age and activity status. Based on Jazcilevich A, Wellens A, Siebe C, Rosas I, Bornstein RD and Riojas-Rodríguez H (2012) Application of a stochastic vehicular wake erosion model to determine PM_{2.5} exposure. *Aeolian Research* 4: 31–37. doi: 10.1016/j.aeolia.2011.11.002.

pollutants. When working at time scales of seconds, features such as increased inhaled dosage in children and specific population, plus relevant spatial and turbulent flow characteristics containing pollutants are obtained. For isolated exposure events, a stochastic modeling scheme was presented that preserved the random character of the phenomena.

Using wind tunnel or in situ experiments with the PI-SWERL device, road soil emissions factors can be obtained as a function of wind speed. Line sources in Gaussian transport models can thus be implemented. The larger the road area, the larger the dust emission. This is clearly shown in road intersections, where emission areas are additive. Gaussian models identify affected areas, where abatement measures can be allocated.

Regarding road-dust effects in human health, further research on the interaction of pollutants and its potentiation could be an important research area. Computational Fluid Dynamics (CFD) to obtain pollution fields at time and space scales in the order of seconds and centimeters is an interesting area of further development in human exposure. Also, abatement measures such as vegetation barriers and optimal routes could be designed and tested using CFD techniques.

Abstract

Soil salination is a major worldwide concern, which affects mainly arable lands, due to irrigation with low quality water and or improper drainage practices that may result in rising of the groundwater level. Many studies have focused on the major negative impacts that soil salination has on soil productivity and associated harmful effects on the agricultural and natural environments. Here, basic soil salination processes and terms are presented, and their impact on soil and crop production is discussed. The chapter also presents key insights regarding common practices used to cope with soil salination and the reclamation of saline soils.

Key points

- Soil salination is a major process of soil degradation.
- Soil salination results from natural (primary) and anthropogenic (secondary) salination processes.
- Major causes of anthropogenic soil salination in arable lands are irrigation with saline water and improper soil drainage.
- Crop development and yield are harmed by soil salination and various practices can be employed to overcome this challenge, including soil reclamation.

Global extent and economic damage to agriculture

Soil is one of the essential resources on the globe, affecting the supply of food, fiber, and clean fresh water, maintaining biodiversity and overall protection of the ecosystem. Soil also plays a central role in the carbon cycle by acting as a major sink. However, globally soil is being continuously depleted due to various degradation processes, with soil salination being a major cause (Ezlit et al., 2010).

Excessive levels of salts occur in large areas of soil around the world and profoundly affect land use. Six percent of terrestrial land is naturally salinized in a process termed primary soil salination, in which salt stored in the soil or groundwater is mobilized to the land surface in the development process of a landscape (Rengasamy, 2006). However, much greater and faster soil salination processes are observed in cultivated lands where 20% of total cropland and 33% of irrigated croplands worldwide are salinized as a result of agricultural practices (Singh, 2015). This type of soil salination, a result of anthropogenic activity, is termed secondary soil salination.

Salinized areas are increasing steadily at a rate of 10% per year and it is estimated that, worldwide, more than 50% of croplands will be salinized by 2050 (Jamil et al., 2011). Naturally, the economic burden of soil salination is considerable, with the global cost of irrigation-induced salinity being in the order of US\$27 billion per year (Qadir et al., 2014).

Fig. 1 Major processes associated with primary and secondary salination (adapted from Maniçoba da Rosa Ferraz Jardim et al., 2020). Light and dark brown colors indicate water saturated and un-saturated terrestrial areas, respectively.

Origin of salinity in soils

As aforementioned, there are two types of controlling factors for soil salination: primary and secondary (Fig. 1). Primary salination results from natural processes including: (i) physical or chemical weathering and transport from parent material, geological deposits or groundwater. This is often observed in closed basins in arid areas, such as the Canadian prairies, where soil leaching is minor and evaporation is high; (ii) geological events, such as volcanic activity or specific formations with high solubility, such as halite (NaCl) that can increase salt concentration in groundwater; (iii) salt water intrusion and tidal fluctuations leading to submergence of low-lying lands by sea water, as observed in many coastal areas worldwide, including the south-east of the United States; (iv) hydrological processes in the presence of shallow and saline groundwater that cause water flow upward by capillarity from the water table to replenish evapotranspiration, subsequently leading to solute accumulation close to the soil surface; (v) deposition of salts by rainfall, mainly along coastal areas, which may account for 10–25% of the total yearly contribution from weathering and is often overlooked.

Unlike primary salination, secondary salination is introduced by human interventions; mainly irrigation with saline water or ill-suited irrigation practices in soils with poor drainage conditions (Ezlit et al., 2010). Modern agriculture in dry areas consumes about 500–1000 mm of water per year while under extreme cases may even consume up to 2000 mm. Globally, and in particular in dry areas, high quality water is in short supply and the use of irrigation water rich in solutes is becoming ever more common. Moreover, overuse of fertilizers through irrigation systems (fertigation) may also increase solute concentration in the irrigation water as farmers frequently add fertilizers in quantities greater than plant demand (Nachshon, 2018). Consequently, the risk of soil salination due to unsustainable irrigation practices with water rich in salt is rising (Rengasamy, 2006).

Salination of cultivated soils

Definition

Salt is an ionic compound formed by the reaction of an acid and a base. Once salt is formed, it may go through cycles of dissolution, transport and crystallization. The salt content of soils above which plant growth is affected depends upon several factors, among which are soil texture, composition of the salt, and plant species. The electrical conductivity (EC) of the saturation extract has been adopted by the US Salinity Laboratory Staff (1954) as the preferred scale for estimating soil salinity, with saline soils being defined as soils with EC exceeding 4 dS m^{-1} .

Classification of water quality by salinity

The criterion for soil salinity ($\text{EC} > 4 \text{ dS m}^{-1}$), as proposed by the US Salinity Laboratory Staff (1954), was determined in saturated water extracts of soils because under this practice water content of the saturated extract can be closely associated with the naturally-occurring state of the soil solution, and can thus be related to plant-growth response. However, the practice of soil saturated water extract is relatively time consuming, and requires high levels of skill, precision, and expertise to reach saturation point, especially in clay soils. Therefore, over recent years it has become more common to determine soil salinity by various soil to

Table 1 Interpretation of 1:1 soluble salts test, for various soil textures (Moebius-Clune et al., 2017).

Degree of salinity	Crop residue	EC (dS m ⁻¹) by soil texture			
		Coarse sand to loamy sand	Loamy fine sand to loam	Silt loam to clay loam	Silty clay loam to clay
Non-saline	Almost negligible effect	0–1.1	0–1.2	0–1.3	0–1.4
Slightly-saline	Yield of the most sensitive crops reduced	1.2–2.4	1.3–2.4	1.4–2.5	1.5–2.8
Moderately saline	Yield of most crops reduced	2.5–4.4	2.5–4.7	2.6–5.0	2.9–5.7
Strongly saline	Only tolerant crops yield well	4.5–9.0	4.8–9.5	5.1–10.1	5.8–11.5
Very strongly saline	Only very tolerant crops yield well	>9.0	>9.5	>10.1	>11.5

water ratio (soil:water) extracts (Kargas et al., 2018). In this practice, the EC of the supernatant of a given soil:water extract (1:1, 1:2, 1:5) is measured by a calibrated electric conductivity meter. Table 1 presents interpretation of EC readings of a 1:1 soil:water extract for different soil textures and related degrees of soil salinity.

The EC readings, correlated to salt concentration expressed in terms of total dissolved solids (TDS, mg L⁻¹), and ionic concentration (mmol_c L⁻¹), for various salt solutions are presented in Fig. 2. Based on these correlations, it is commonly accepted for a mixture of salts to refer to the relationship between TDS and EC for various salt solutions as follows (Rhoades, 1996):

$$\text{TDS} = 640 \times \text{EC} \quad (1)$$

where EC is in units of dS m⁻¹.

As can be seen from the data in Fig. 2, the EC of soil is not only determined by the concentration of ions but also by the characteristics of the ions or salinity chemistry (US Salinity Laboratory Staff, 1954). Consequently, the ionic composition of the soil solution should also be taken into account for proper interpretation of salinity stress and soil-plant interactions (Rengasamy, 2010). In general, in the Commonwealth of Independent States (CIS, formerly the USSR) and many other countries, classification of soil salinity is based on total soluble salts (TSS, %; g salt 100 g⁻¹ dry soil), and salinity chemistry which is determined by the concentration ratios of anions (HCO₃⁻, Cl⁻, SO₄²⁻) and additionally by cations (Na⁺, Ca²⁺, Mg²⁺) in 1:5 soil–water extraction (meq L⁻¹). This type of classification suggests that together with the TSS, the threshold level or toxicity of salts (highly soluble salts in toxic quantities to plants) is associated with the relation between anionic and cationic ions, i.e., type and degree of salinity. Recently, Ismayilov et al. (2021) stated that once the salinity type of the soil is established, EC (1:5) values can be safely used for evaluation of the degree of soil salinity in irrigated land in the context of sustainable soil and crop management.

Fig. 2 Relationship between salt concentration and electrical conductivity of various salt solutions: salt concentration in (A) millimoles of charge per liter and (B) milligrams per liter. Adapted from the US Salinity Laboratory Staff (1954) Diagnosis and improvement of saline and alkali soils. *Agriculture Handbook*, vol. 60, pp. 83–100, US Salinity Laboratory Staff.

Salt dissolution, transport, and precipitation

Many salts are relatively soluble in water, as the electrostatic attraction forces between water dipoles and the anions and cations forming the salt exceeds the attraction forces between the positive and negative ions that compose the salt (Hillel, 2000). Consequently, pore water and surface water may dissolve crystalline salts that are found in the soil, and transport the solutes in the water by diffusion and advection (Hillel, 2000; Nachshon, 2018).

Salt accumulation and precipitation in cultivated soils is usually a result of evaporation and transpiration processes. These processes take the pore water out of the soil, while leaving behind the solutes that are dissolved within. Consequently, pore water solute concentration increases until saturation is reached and salt crystals begin to precipitate. Salt precipitation usually occurs as narrow layers at the upper boundary of the evaporation front or near the roots, where water uptake by the roots takes place (Nachshon, 2018). When the evaporation front is at the soil-atmosphere interface, salt accumulates at the soil surface either as an efflorescent (above soil surface) or as a subflorescent crust (below soil surface), depending mainly on salt type. A conceptual scheme of root zone soil salination due to upward capillary flow of water from a shallow-saline aquifer and transport of solutes upwards, towards the soil surface and the root system, where evaporation and transportation are taking place is presented in Fig. 3. These processes result in the accumulation and precipitation of salt in the soil. At locations where the capillary flow reaches the soil surface, the salt precipitates as an efflorescent salt crust.

Effect of salination on soil

Effects on the soil ecosystem

The recent review of Daliakopoulos et al. (2016), and references cited therein, highlights the role of soil salination in determining ecological soil functions. Salination may negatively affect soil respiration, residue decomposition, nitrification, and denitrification through a decrease in soil biodiversity and microorganism activity that often lead to loss of soil organic matter. Loss of the latter enhances aggregate destabilization and soil sensitivity to wind and water erosion. Moreover, extreme salination could result in eliminating all vegetation, leaving the soil bare and thus more susceptible for further physical degradation. Yet, naturally saline soils may comprise unique gene reservoirs that deserve protection.

Fig. 3 Conceptual scheme of soil salination due to upward transport of solutes towards the soil surface with capillary flow. At the soil surface and the root system, roots and evaporation are consuming water and salts accumulate and precipitate in the upper parts of the soil profile, as an efflorescent salt crust where capillary flow reaches the soil surface, and as subflorescence where the water table is too deep and the capillary flow does not reach the soil surface.

Effects on soil properties

Salt precipitation, especially subflorescence precipitation, greatly affects soil mechanical properties as salt crystallization may lead to soil cementation that holds sand and silt particles together and increases the shear strength and stiffness of the soil during the drying process. On the other hand, in cohesive (rich in clay and/or organic matter) soils, subflorescence salt crystallization may enhance weathering processes and reduce soil aggregate stability as the crystallized salt at the pores applies pressure against the pore walls that leads to disaggregation (Nachshon, 2016). Furthermore, subflorescence salt precipitation in the soil pores changes the hydrological properties of the soil and reduces percolation and evaporation processes as it reduces matrix porosity, permeability and vapor diffusivity. Salt precipitation as efflorescent salt crust has less effect on physical properties of the soil-matrix itself, as crystallization occurs above the soil surface. Nevertheless, efflorescent salt precipitation strongly affects evaporation because it alters conditions at the boundary layer between the soil and the atmosphere.

In salt affected soils that are also sodic, i.e., soils in which the sodium adsorption ratio (SAR) is greater than 5, the soil is considered a sodic soil and the conditions may adversely affect soil structure and stability, and subsequently the growth of most crop plants. However, the interrelationship between the SAR of an equilibrium solution and EC of the soil solution is central in dictating whether sodic or non-sodic behavior (i.e., swelling and dispersion of soil clay) will be observed (Levy and Nachshon, in press).

Impact of salination on plants

The negative effects of salinity on plant growth are related to: (i) lowering of soil solution osmotic potential; (ii) specific ions toxicity, and (iii) nutritional imbalance.

Reduction of the osmotic potential between soil pore water and plant root cells, because of an increase of soil pore water solute concentration, leads to restrained water uptake by plants and reduces their ability to survive and produce, especially in arid areas (Rengasamy, 2006; Nachshon, 2018). The osmotic pressure, P_o [kPa], of a solution is a colligative property and is related to the total salt concentration rather than the concentration of individual ionic species. Therefore, P_o can be estimated from the solution electrical conductivity expressed in units of dS m^{-1} (Rhoades, 1996):

$$P_o = 0.36 \times \text{EC} \quad (2)$$

Certain solutes which accumulate in plants over time can negatively affect various biological functions of the plant. For example, high concentrations of boron, chloride, sodium and carbonate are toxic for many plants and result in the drying of leaves, damage to fruit, and can affect root growth (Munns and Tester, 2008; Nachshon, 2018). Excess salinity may also cause nutrient deficiencies or imbalances due to the competition between sodium and/or chloride and nutrients such as calcium, potassium and nitrate, which are essential for plant development (Hu and Schmidhalter, 2005).

Crop yield and soil salinity

For agricultural purposes, salt tolerance of crops is described by various response functions that correlate soil salinity to yield reduction. The first correlations that were developed described a linear reduction of yield as salinity increases (Magistad et al., 1943; Nachshon, 2018). Later on, it has been recognized that crop yield is not reduced until a threshold salinity level is exceeded, beyond which the yield decreases linearly with rising salinity. Further research has presented more complicated functions that correlate yield with soil salinity by exponential ratios (Steppuhn et al., 1998) and a combination of two and three linear segments that describe different stages of crop response to salinity (Shani and Dudley, 2001), as demonstrated in Fig. 4.

Today, the function of van Genuchten and Hoffman (1984) is still widely used to describe percentile reduction of yield (f_{EC}) as a function of the soil saturated paste electrical conductivity (EC_e):

$$f_{\text{EC}} = \frac{1}{1 + \left(\frac{\text{EC}_e}{\text{EC}_{50}}\right)^P} \quad (3)$$

where EC_{50} is the electrical conductivity of a soil saturated paste that leads to a 50% reduction in yield, P is a plant parameter, that in many cases is equal to 3 (Shani et al., 2007). Typical values of EC_{50} , for various crops are described in the literature, and selected samples are presented in Table 2 (Shani et al., 2007; Nachshon, 2018).

Plants can be divided into four groups (sensitive to tolerant) according to their response to salinity. Of the field crops, *Hordeum vulgare* L. (barley), *Gossypium herbaceum* L. (cotton), and *Beta vulgaris* L. subsp. *vulgaris* (sugar beet) belong to the tolerant group, *Triticum aestivum* L. (wheat) and *Glycine max* (L.) Merrill (soya bean) belong to the moderately tolerant group, *Arachis hypogaea* L. (peanut) and *Oryza sativa* L. (rice) belong to the moderately sensitive group, and *Phaseolus vulgaris* L. (beans) and *Vigna unguiculata* L. (cowpeas) belong to the salt-sensitive group.

Moreover, plant response to salinity depends also on soil, climate, and plant factors. Soil-water content and frequency of irrigation affect the tolerance of crops to soil salinity. Shortening the irrigation interval minimizes the deleterious effects of salinity.

Fig. 4 (A) Relative dry matter (DM), and (B) yield ($Y Y_{max}^{-1}$), for corn (A) and melon (B) as affected by normalized irrigation (the ratio of irrigation [I] to potential evaporation [E_0]) and salinity treatments. Table 2 The EC_{50} values of selected crops.

Crop	EC_{50} [dS m ⁻¹]
Sunflower	10
Melon	7.5
Tomato	5.5
Corn	5
Pepper	2.5
Grape	2.5
Onion	3

The salt tolerance of many crops is enhanced when daily drip irrigation is used. Climate can also modify plant response to salinity with tolerance to salt often being reduced under hot, dry conditions.

Plant factors such as stage of growth, variety, and rootstock also affect plant response to salinity. Rice, barley, wheat, and corn are most sensitive to salinity during the early seedling stage. Sugar beet and sunflower (*Helianthus annuus* L.) are more sensitive to salinity during germination than in later stages of growth. Salinity effects on the vegetative growth of many plants (e.g., cotton, wheat) are greater than on seed or fiber production. In general, salinity suppresses top growth more than root growth. The type of rootstock of woody plants may also affect the specific tolerance of fruit crops to salinity.

Salinization management

Monitoring salt affected soils

Managing of salt affected soils requires knowledge of their location. Hence, monitoring the development of and mapping of soil salinity are central for effectively handling such soils. Mapping of salt affected soils at a global scale by remote observations (satellites, aerial photograph) may illustrate the scope of the soil salinization problem. Yet, it should be born in mind that, typically, remote observations of soil salinity can identify salt features on the soil surface in the visible spectrum, or through multispectral and hyperspectral remote sensing indices that depict only surface soil properties or vegetation health that can serve as a proxy for salinity.

However, mapping at a regional, farm or field scale is necessary for the design of management practices needed for alleviating the salinity problem. Salinity monitoring at farm or field scale have traditionally been carried out using local salinity sensors and soil sampling. In recent years, use of non-invasive geophysical techniques such as electromagnetic induction (EMI) (Hendrickx et al., 1992), vertical electrical sounding (VES) (Masoud et al., 2019) and electrical resistivity tomography (ERT) (Rasul et al., 2018) are gradually being adopted. However, for optimal use of data collected by these means, especially for mapping subsurface soil salinity, the measurements should be combined with actual ground data.

Finally, multi-scale integrated assessments that imply a combination of remote sensing, field data and various modeling approaches can improve the development of soil salination risk maps, useful to land managers and users. Fig. 5 presents an example of a soil salinity and sodicity risk map produced by Daliakopoulos et al. (2016).

Fig. 5 Distribution of saline and sodic soils in terms of agricultural constraint and as primary and secondary limitations to agricultural use, and areas of seawater intrusion in Europe. From Daliakopoulos IN, Tsanis IK, Koutroulis A, Kourgialas NN and Varouchakis AE (2016) The threat of soil salinity: A European scale review. *Science of the Total Environment* 573: 727–739.

Coping with soil salinization

Like most other environmental concerns, the best way to cope with soil salination is to prevent it by using good quality water for irrigation, avoid land-use changes and agricultural practices that reduce infiltration and soil leaching processes. However, good quality water is in short supply in many areas, especially dry areas, where the need for irrigation is high, precipitation is low and is exceeded by evapotranspiration (Nachshon, 2018). Therefore, it is essential to improve agricultural and irrigation practices in order to maintain flourishing and sustainable agriculture in saline environments.

To avoid salt accumulation in the root zone during repeated cycles of irrigation and evapotranspiration, the common remedy is to apply water in volumes greater than evapotranspiration to deliberately cause a fraction of the applied water to flow downwards through the root zone and flush away the excess salts.

The required volume of excess water to leach the salt downwards is termed the 'leaching requirement' (LR). The LR is a function of irrigation EC (EC_i) and required EC of the saturation extract water from the root zone soil (EC_t) to ensure a yield reduction less than 10%:

$$LR = \frac{EC_i}{EC_t - EC_i} \quad (4)$$

The EC_t values for different crops can be found in the literature (Shani et al., 2007).

Although the practice of leaching is effective with respect to salt leaching from the root zone, it has three negative aspects: (i) it reduces water-use efficiency because more water is needed for irrigation; (ii) in the case of irrigation with saline water, the elevated volume of water used for irrigation results in an increase of net mass of salt that is added to the soil environment; and (iii) under conditions of poor drainage, it may cause groundwater levels to rise and water logging, which further increases the risk of soil salination and reduction of yield.

To avoid the rising of groundwater levels, artificial drainage systems of the soil profile may be implemented. The artificial drainage of groundwater is generally carried out by means of drains that could consist of ditches, pipes, or 'mole channels' into which groundwater flows as a result of the hydraulic gradients existing in the soil. The drains themselves are made to direct the water, by gravity or by pumping, to a drainage outlet, which may be a stream, a lake, an evaporation pond or the sea. In some places, drainage water may be recycled or reused for agricultural, industrial or residential purposes, as well as for agroforestry or the irrigation of ornamental plants. Because drainage water may contain potentially harmful concentrations of salts, fertilizer nutrients, pesticide residues, and various other toxic chemicals, as well as biological pathogens, it is not enough to provide a means for 'getting rid' of it; attention must be paid to the quality of the water to be disposed of and to the long-term consequences of its disposal.

Reclamation of salt affected soils

In ideal soils under piston flow conditions, the EC of soil water and the applied water would be equal after the passage of one pore volume of rainfall or irrigation water. However, water flow in soils is not ideal for two reasons: (i) water flows faster through soil cracks and large pores between soil aggregates than through smaller pores within aggregates. This difference in localized water flow velocities is commonly referred to as 'bypass flow,' or 'preferential flow'; (ii) salt diffusion and chemical reactions are not sufficiently rapid to allow salt concentration to be the same for all pores of differing sizes, particularly during periods of rapid water movement.

Salt transport models have provided considerable insight into these processes. However, suitable mathematical models are not available to describe the multiple concurrent processes of water flow, including spatially variable hydraulic properties and all the chemical reactions—exchange, dissolution, precipitation, and CO_2 liquid-gas equilibria—involved in salt transport at the field scale. Consequently, reclamation guidelines are largely based on experimental relations obtained from field and lysimeter reclamation experiments.

The method of water application and soil type are the primary variables affecting the amount of water required to reclaim saline soils. For saline soils, 60% or more of the salts initially present is leached by a depth of water equal to the depth of soil (Fig. 6A) under continuously ponded conditions. Sandy loam soils with low saturated water contents have greater leaching efficiency than clay loam or clay soils (Fig. 6A). Soil pores in sandy soils are more uniform in diameter than in clay loam or clay soils. The finer-textured soils can have large cracks with large pores when dry, and fine pores within aggregates when wet. Such bypass channels reduce leaching efficiency. The water requirement for leaching can be reduced by the intermittent application of ponded water, particularly for fine-textured soils (Fig. 6B). Under intermittent ponding, unsaturated conditions prevail in the soil profile and the inefficient bypass flow in large cracks and pores is prevented. Similarly, with sprinkler irrigation, reclamation occurs under unsaturated conditions and the efficiency of leaching increases. Sodic clay soils tend to suffer from swelling and dispersion processes that reduce their hydraulic conductivity and affect their soil structure and stability. This can be moderated by the addition of gypsum (calcium sulfate, $CaSO_4$) or other substances that contribute divalent cations to the soil (see Levy and Nachshon, in press).

In the case of extreme soil salination conditions, where soil leaching and drainage practices are impractical and conventional agriculture is impossible, one may use halophyte species for agriculture. Halophyte crops include domesticated wild species that are resilient to salinity and produce edible yield and useful biomass. The development of halophytic species for agriculture has great potential as it will generate new croplands in areas that currently are not suitable for agriculture such as the coastal areas and very saline inland areas. Furthermore, halophyte plants (e.g., *Salicornia bigelovii* Torr) can be used to reclaim saline soil, as some plants may extract salt from the soil with the water consumed, and accumulate it in their tissues (e.g., *Suaeda maritima* (L.) Dumort and

Fig. 6 Depth of leaching water per unit depth of soil required to reclaim a saline soil by continuous ponding (A) and depth of leaching water per unit depth of soil required to reclaim a saline soil by ponding water intermittently (B). Adapted from Oster JD, Shainberg I and Abrol IP (1996) Reclamation of salt affected soils. In Agassi M (ed.) *Soil Erosion Conservation and Rehabilitation*, pp. 315–342. New York: Marcel Dekker.

Sesuvium portulacastrum (L.) L). In addition, control of soil erosion in saline environments may be achieved by the use of halophyte plants that stabilize soil structure with their roots (e.g., *Atriplex lentiformis* (Torr) S. Wats). This type of soil reclamation, termed phytoremediation, has the potential to be a cost-effective and an environmentally sound technology for remediation of salt impacted soils (Hasanuzzaman et al., 2014; Nachshon, 2018).

Summary

Soil has always been a valuable resource for mankind, but the ever growing world population applies an significant increasing pressure on cultivated lands that has turned them into a limited resource because soil has a very long formation period (in the order of thousands of years). Therefore, if not handled in a sustainable manner, soils, particularly those suited for agricultural activities, might be in short supply in a few decades. Under arid and semiarid conditions, and in regions of poor natural drainage, there is a real hazard of salt accumulation in soils. The processes by which soluble salts accumulate in soils include irrigation with water containing salts, upward movement of moderate-to-saline water from high water tables, and weathering of primary and secondary minerals in the soils. Accumulation of soluble salts in the soil solution imposes stress on crop development and growth that can lead to decreased yields and, in severe cases, complete crop failure. Use of poor-quality water is increasing due to growing municipal demand for good-quality water and the need to dispose of municipal wastewater and agricultural drainage water. As a result, a better understanding of the reclamation of salt affected soils is becoming an increasingly important component of water and soil management to ensure the long-term sustainability of irrigated agriculture.

Abstract

Soil structure and soil organic matter (SOM) have an interactive relationship and mediate all soil processes at all spatial and temporal scales. Soil structure and SOM can be degraded through land use, tillage, compaction, and climate change mechanisms. This impacts on the ability of soil to execute its soil functions and ecosystem services such as net primary productivity, regulation of water and air, biodiversity support, and climate change mitigation. Management interventions, particularly in agriculture, may slow or reverse degradation of soil structure and SOM, although there is much that future research can focus on to increase our knowledge.

Glossary

Alkyl A functional group of an organic chemical containing only carbon and hydrogen atoms arranged in a chain, considered to be more difficult for soil microorganisms to decompose.

Arbuscular mycorrhiza fungi Fungi which form a symbiotic association with plant roots for mutual benefit in exchanging nutrients and carbon.

O-alkyl A functional group mainly representing carbohydrates, including cellulose and hemicellulose, in fresh plant material, considered to be labile for soil microorganisms.

Plastic limit Occasionally referred to as the lower plastic limit, this is the water content above which the soil passes from a non-plastic to a plastic consistency state, indicating the 'workability' of the soil.

Suberin A complex plant macromolecule, common in roots, formed of long-chain fatty acids which form a protective barrier against water and solute movement.

Key points

- Soil structure and soil organic matter (SOM) have an interactive relationship, mediating all soil processes at all spatial and temporal scales, and a degradation of one will impact the other.
- Soil structure and SOM are degraded by a variety of mechanisms and processes, including land use, tillage, compaction, and climate change.
- Soil structure and SOM degradation affect the ability of soil to carry out its functions in support of wider ecosystem services, including net primary productivity, regulation of water and air, biodiversity support, and climate change mitigation.
- Management interventions can slow or reverse degradation of soil structure and SOM, such as modifying agricultural practices to retain or increase SOM, minimizing soil mechanical stresses to reduce soil structure degradation, and proactively remediating previous degradation.
- Future research should exploit recent advances in the non-destructive characterization of soil structure, the physical, biological, and chemical characterization of SOM, and modeling, to increase our understanding of the interactive relationship between soil structure and SOM.

Nomenclature

C	Carbon
C ₂ H ₄	Ethylene
Ca	Calcium
CH ₄	Methane
CO ₂	Carbon dioxide
K	Potassium
Mg	Magnesium
Mn	Manganese
N	Nitrogen
N ₂ O	Nitrous oxide
NH ₃	Ammonia
NO ₂	Nitrate
P	Phosphorus
S	Sulfur
SOM	Soil organic matter

Introduction

Soil structure and soil organic matter (SOM) have an interactive relationship. Soil structure is the spatial architectural arrangement of solid primary particles, either separately or more commonly in secondary agglomerated units (aggregates), with the associated non-solid pore network. Amongst other mechanisms, aggregates can be created by SOM components, such as the initiation of aggregation through clay mineral adsorption and alignment on particulate SOM. Aggregates can then be stabilized by other SOM components, notably microbial products or the living microorganisms themselves. In turn, SOM components can be sequestered and protected physically in stabilized aggregates or on mineral surfaces. Other SOM components will turn over in a functioning soil. In short, soil structure and SOM are interdependent.

In natural systems soil structure and SOM are controlled by soil forming factors. In classic pedology theory these factors are climate, organisms, relief, parent material and time. The same factors are also important in non-natural systems, but with the additional factor of management. All agricultural and forestry systems have a strong management factor which impacts on many soil properties and functions. In agricultural and forestry systems, it can be argued that soil structure and SOM are controlled more by management than any of the other pedological factors.

In many non-natural systems, management practices and interventions can often lead to a degradation of soil structure and SOM where the main objective is not based directly on enhancing these. In agricultural systems, for instance, soil structure and SOM can be degraded in the course of interventions imposed to maximize crop or livestock productivity. This is not always the case however as it is recognized increasingly that soil structure and SOM are key to achieving any main objective, and sometimes positive interventions are made. It is also the case that soil structure and SOM can degrade in natural systems too.

Structure and SOM are dynamic properties of the soil and are key to the ability of the soil to carry out its functions in support of wider ecosystem services. Soil structure and SOM mediate all soil processes at all spatial and temporal scales. Degradation of soil structure and SOM are therefore undesired in a healthy soil. Degradation of SOM may relate to either a measurable loss of the total quantity of SOM, or a decline in the quality of SOM particularly with respect to soil functioning, or both. The greater part of SOM is comprised of carbon (C), and hence this can have implications for the global C cycle and climate change. This article gives a very generalized summary of the interactive degradation of soil structure and SOM. It describes the main causes and effects of degradation on soil structure and SOM, the subsequent effects on soil functions, and an outlook to the future in this area.

Causes of soil structure and SOM degradation

There are many natural or management-imposed mechanisms which can lead to the degradation of soil structure and SOM. This article is not exhaustive, but four principal themes known to affect soil structure and SOM interactively are discussed below: land use; tillage; compaction; and climate change (Fig. 1).

Land use

The way in which land is used has a great control on both soil structure and SOM, and this can lead to their degradation (Young et al., 1998; Ferreira et al., 2022) (Fig. 2). In soil under long-term land use, SOM attains an equilibrium based on the balance between inputs and outputs (Johnston et al., 2009). Soil under natural and semi-natural systems, and agricultural and forestry soils

Fig. 1 The main causes of interactive degradation of soil structure and soil organic matter (left) and the effect on soil functions and ecosystem services (right).

Land use	Tillage	Compaction	Climate change

Fig. 2 A summary of the causes of interactive degradation of soil structure and soil organic matter.

under long-term perennial vegetation, have greater SOM contents compared to agricultural soils under annual crops (Sanderman et al., 2017). Perennial systems have a continuous vegetative covering with a constant source of organic inputs through leaf litter and root exudates. They also support a healthy soil biology and microbiology which process such organic inputs. Contrastingly, soils under annual systems generally have smaller organic inputs to the soil because much of the above-ground biomass is harvested and removed. Such systems also tend to be disturbed by cultivations or tillage, which encourages the loss of SOM. The intensity of management of annual systems is an important factor. Systems where management intervenes to apply organic amendments, or to include phases of grass leys in crop rotations, will suffer less degradation of SOM (Johnston et al., 2009). However, this lesser degradation of SOM through use of organic amendments may only be felt in the topsoil, unless applied at very high rates, with subsoils still degraded in SOM beyond what they would be in comparable perennial systems.

It follows that any change in land use affects SOM. Degradation of SOM usually follows a change from natural to semi-natural to perennial to annual systems (The Royal Society, 2020). Typical degradative land use changes are from woodland or grassland to arable systems (Fig. 3). This has been a land use change that has been present over the course of human history as increasingly more land has been put into agricultural production. Restorative land use changes such as taking land out of annual arable systems and back into grassland can restore SOM, but experience shows that it is much harder and slower to regain SOM compared to the rapidity with which SOM can be lost (Or et al., 2021). It can take several decades for soil to adjust to a new land use (Johnston et al., 2009).

A change in land use can also lead to changes in the biochemical characteristics of SOM (Shepherd et al., 2001). Different plant types will have different compositions of compounds and functional groups. Compounds such as amino acids, organic acids and celluloses tend to be labile, or available to microorganisms, whereas fats, waxes and lignins tend to decompose at a much slower rate. There is also a range of functional biochemical groups, such as O-alkyl C and alkyl C groups which are, relatively, available and stable, respectively, though that is a generalization and overall decomposition rates are also controlled by accessibility. Biochemistry is also controlled by the plant part it derives from. For instance, the macromolecule suberin is particularly abundant in root tissue and is believed to be highly resistant to decomposition. The biochemical composition determines bioavailability by controlling the enzymatic rates required for microorganisms to process. Another factor affecting bioavailability to microorganisms is the C-to-nitrogen (N) ratio (C:N). Application of some organic amendments in agriculture can reduce C:N ratios, which favors faster decomposition. In general, systems with a greater diversity of above-ground vegetation will support a greater diversity of SOM in the underlying soil than systems with reduced diversity.

Shifts from perennial grassland or woodland systems to annual arable systems that degrade SOM often cause degradation of soil structure. Rapid reversal of decades of structure formation can occur following land use change. Loss of SOM leads to a loss of structural stability, particularly the stability of soil aggregates (Tisdall and Oades, 1982; Shepherd et al., 2001). This is manifest in a decrease in the mean size of stable aggregates. Land use change has been shown to have a particular effect in reducing particulate SOM content which is thought to contain many of the structural stabilizing components. Loss of soil structure can be evident in a decrease in overall porosity. Larger water-transmitting pores (macropores) are affected more so than smaller water-retaining pores (micropores). Interventions such as the application of organic amendments in arable systems can arrest these declines to some

Fig. 3 Soil cores taken from the Highfield Ley-Arable long-term experiment at Rothamsted Research (UK), approximately 60 years after land use change from existing perennial grassland (left) to annual arable (center) or permanent bare fallow (right). Note the loss of the darker organic layer in the soils under arable and fallow treatments compared to grass.

extent, though the effects are generally only felt in the topsoil. Such amendments tend to increase the particulate SOM content which is linked to soil structure improvement.

Soil structure degradation increases susceptibility of a soil to raindrop impact in annual arable systems where there is a discontinuous vegetative cover of the soil surface. Soil structure decline can be associated with an increase in fine soil particles that are readily-dispersed. Such dispersed soil particles can form a hard seal of aligned particles upon drying to create a surface crust. Surface crusts can be slowly- or completely impermeable compared with an open stable structure often associated with perennial systems (Dexter, 1988). This has implications for the amount of water that can enter the soil, and the availability of water to growing plants and crops.

Loss of SOM can also degrade soil structure by increasing the susceptible to forces of rapid wetting. SOM can impart a degree of hydrophobicity on soils, particularly below a critical water content threshold where there is an inverse relationship between SOM and soil wetting rate (Kay, 1998). Rapid wetting rates of dry soil under annual cropping systems can cause slaking where air entrapped within aggregated structures rapidly increases in pressure to cause an implosion (Tisdall and Oades, 1982; Dexter, 1988; Hallett and Bengough, 2013). In contrast, organic compounds supplied in perennial system increase bond strengths of aggregates and slow the wetting rate through increased hydrophobicity or water repellency. Extracellular polymeric substances, common in non-degraded soil, have been found to reduce the rate of wetting and drying (Hallett and Bengough, 2013).

An extreme example of land use change is soil sealing, where the soil is permanently covered by artificial surfaces of urban areas or infrastructure in the built environment (Huber et al., 2008). This can degrade the structure of the remaining underlying soil due to increased overburden pressures (Ferreira et al., 2022). Although existing SOM can be protected against further mineralization through being sealed, there is often a net loss of SOM from removal of SOM-rich topsoil, and there are few practical opportunities to increase SOM stocks of sealed soil.

Tillage

Tillage or cultivation is the most significant form of mechanical disturbance to the soil and has been described as the largest land engineering operation on the planet (Or et al., 2021). Tillage is conducted to prepare the soil for a crop. 'Conventional' tillage often involves use of a moldboard plow to invert the upper soil layer (typically 20 cm or so), and this continues to be common. Secondary

tillage treatments may then follow, such as use of disks or power harrows to break up soil. Much interest now is on reducing the impact of tillage on the soil, with variations that might be umbrella-termed 'reduced' tillage which includes minimum or shallow tillage, right through to completely zero tillage (also synonymous with direct drilling). Reduced or zero tillage often form a basis of wider agricultural strategies including conservation agriculture and regenerative farming. The full effects of any kind of tillage are site-specific, but for some cropping systems and regions, particularly aridic zones, this is a feasible option.

The rationale and benefits of conventional tillage for soil structure are to modify the structure to break up problematic structures such as surface crusts and large clods to create a seedbed with a range of aggregate and pore sizes (Dexter, 1988; Hallett and Bengough, 2013; Or et al., 2021). Aggregate size variation ensures good seed-soil contact. Aggregates formed through tillage are more likely to be spherical shaped rather than irregular, which generate a porous structure. The variation in pore sizes is important to maintain or create both larger pores to keep the seedbed aerobic and smaller pores that retain plant-available water. Conventional tillage reduces surface roughness which is important for uniformity of seed placement depth and germination. When conducted at the correct time when the soil is friable, typically when just drier than the soil plastic limit (Dexter, 1988), it can improve structure by creating a seedbed and incorporating SOM. This can be a great benefit of conventional tillage to SOM in that it is incorporated below the surface where it is more likely to be protected. Other benefits of tillage include controlling weeds, pests and pathogens arising from the previous crop (Hallett and Bengough, 2013).

Despite these benefits, conventional tillage is often associated with degradation of soil structure and SOM (Fig. 2). Tillage affects structure-forming and stabilizing agents negatively (Shepherd et al., 2001). Plant root exudates help to bind soil particles into aggregates, but tillage can disrupt these and reverse the process. Fungal hyphae are a key aggregating agent as they physically enmesh soil particles together (Kay, 1998). Hyphae are easily destroyed by tillage causing loss of structure (The Royal Society, 2020). Arbuscular mycorrhiza, believed to play a key role in aggregate stability, are particularly affected by tillage (Tisdall and Oades, 1982). Glomalin is a protein produced by arbuscular mycorrhiza fungi which has been shown to respond rapidly to changes in tillage to impart stability (Redmile-Gordon et al., 2020), although the full effects are not fully established and are almost certainly context-specific (Goss and Kay, 2005). Soil structure degradation can sometimes be observed following land use change from undisturbed to tilled systems before noticeable differences in SOM are measured. This has been ascribed to the changes in fine roots and fungal hyphae. At the soil surface, tillage exposes soil to raindrop impact which can increase erosion rates. Aggregates created by tillage are not as stable as those formed in natural systems. Tillage also negatively affects soil macrofauna, most notably earthworm species (*Lumbricus*). Often biopores (those created by macrofauna) are the key component of the soil macroporosity (Or et al., 2021).

Conducted at the wrong time, tillage can degrade soil structure (Fig. 4). Tillage is best suited to periods when the soil is in a brittle condition close to the lower plastic limit for the preparation of seedbeds. As finer-textured soils have a greater range of plasticity than do coarser-textured soils, they are particularly susceptible to plastic deformation when tilled under wet conditions (Hallett and Bengough, 2013). The pore network can be adversely affected—particularly the water-transmitting macropores. Inappropriate or ill-timed tillage can create an impermeable pan at the maximum depth of the plough inversion—termed a plough pan—particularly where there is repeated smearing at the same depth of the plough moving over wet soil (The Royal Society, 2020). Increases in porosity from tillage can be short-lived if the loosened soil slumps when wetted due to aggregate instability. Some finer-textured soils can recover from tillage-induced plastic deformation through wet-dry cycles (and freeze-thaw cycles) that cause shrinking and swelling of the soil—a process that has been termed 'self-mulching'.

Fig. 4 Conventional tillage by moldboard plough (seen here on the Broadbalk Winter Wheat classical experiment at Rothamsted Research, UK) is designed to create a seedbed when the soil is in a brittle state close to the plastic limit, but when conducted under wet conditions tillage can lead to smearing, plastic deformation and degradation of soil structure.

Conventional tillage increases the oxidation of SOM causing its loss. Tillage negatively affects macrofauna populations with implications for SOM. Deep-burrowing earthworms and bioturbation are a key process by which SOM is delivered to the subsoil where it can be stabilized under localized conditions that lessen or prevent oxidation and mineralization. The soil plastic limit—an index important for predicting soil mechanical behavior—is linked to SOM. Soils depleted of SOM have been found to have lower plastic limits meaning that the risk of degrading soil through plastic deformation is at a smaller water content when soils of greater SOM would be in a more brittle state suitable for seedbed preparation (Obour et al., 2018). To minimize the potential for soil structure degradation, such soils may have to be tilled when drier, reducing the window for soil operations. This is important for hard-setting soils (Dexter, 1988).

Reduced or zero tillage in arable agriculture can lessen SOM and soil structure degradation through reducing soil disturbance and maintaining crop residues. Comparison of different tillage practices on SOM have to be made with care however and with reference to soil depth. Apparent improvements in soil structure and SOM in the topsoil (e.g., an increase in topsoil SOM from reduced tillage) might actually be more reflective of a change in the vertical distribution of SOM rather than an overall change (e.g., if SOM is buried below the topsoil under conventional tillage).

Compaction

Compaction is the process whereby soil loses pore volume and hence increases in bulk density. Compaction can be due to natural causes, such as compression in the subsoil arising from overburden stress, and densification in non-rigid fine-textured soils as they shrink upon drying. Localized compaction occurs naturally as plant roots elongate into the soil and necessarily push soil particles together to create the volume for expansion (Dexter, 1988). More often though, compaction is caused by the way in which soils are managed. Very occasionally, compaction is a desired objective in specific circumstances such as the use of soil for foundations and engineering works. Some degree of compaction can be beneficial to achieve good seed-soil contact and to reduce the risk of crop lodging in soils under arable systems. Commonly however, compaction is a degradation process than has clear deleterious effects on soil structure and SOM (Dexter, 1988; Ferreira et al., 2022) (Fig. 2).

Compaction in agricultural systems is largely caused by the use of traffic and machinery to conduct operations (Ferreira et al., 2022). Routine operations such as tillage, drilling, fertilizer application, and harvest are mostly conducted by tractor-powered machinery. In intensive agricultural systems the machinery and loads have tended to increase over time. The extent of compaction is dependent on a number of factors, including ground contact pressure, the number of passes and the porosity and stability of the soil. Wheeling by traffic under wet conditions can deform the soil through shear stresses. Compaction can also occur in agricultural soils under grazing livestock systems (Hu et al., 2021). The compaction pressures under the hooves of larger livestock, such as cattle, can be similar to those of larger tractors, and equally degrading under wet conditions. Some regions have seen significant increases in both the stocking density and the average mass of livestock under some intensive systems. When combined with over-grazing, grassland compaction can be severe, although it is less-well characterized compared to traffic-induced compaction in arable systems.

Compaction increases bulk density. There is often a non-uniform propagation of stress down the soil profile, though this can vary with the equipment used. Compaction-induced porosity loss is not evenly distributed amongst the pore sizes. The water-transmitting macropores are affected most, and there is a corresponding loss of air capacity and pore connectivity (Kay, 1998). Some SOM-stabilized biopores are able to resist compaction more so than pedological macropores however. There is often a change in the alignment of pores from predominantly vertical towards predominantly horizontal, with an associated platy soil structure. This anisotropy of the soil pore network has implications for the hydraulic functioning of soil and gaseous exchange processes (Ferreira et al., 2022), root growth and burrowing by soil fauna.

Soil strength is increased through compaction. Strength can increase to such an extent that root penetration is impacted or prevented completely (Fig. 5). Compaction can cause the creation of an impenetrable pan. This has deleterious effects on the ability of plants to grow. Roots respond to soil structure change due to the effects on cell division and expansion rates. This is manifest in retarded root elongation and increases in root diameter as they expand radially, rather than longitudinally, and thicken in strong soil (Hallett and Bengough, 2013). Root systems are often shallow and restricted to the upper soil layers as a result. Signaling between roots and shoots can then affect above-ground plant growth and crop yield. Studies have shown reactive oxygen signaling and ethylene and auxin responses which control root growth characteristics upon encountering mechanically-hard layers in soil, including 'bending' of roots and proliferation of root hairs to try and explore a way around the obstacle (Jacobsen et al., 2021), with repercussions for leaf growth, morphology, and stomatal closure.

Compaction-induced soil structure degradation can affect SOM. Plant-derived SOM is reduced where plant growth is retarded by compaction. Leaf litter inputs are reduced consequently. Of particular importance is the distribution of roots in the soil profile, which are typically restricted to the upper soil layers where compaction is present (Hallett and Bengough, 2013). The loss of SOM can reduce the resilience of the soil to withstand further physical stresses. SOM affects the ability of soil to compact at smaller stress compared to greater stresses. Under specific conditions however, compaction has been linked to a reduction of SOM loss likely due to reduced loss of dissolved SOM through reduced infiltration (Deurer et al., 2012).

Tillage can reduce bulk density in the upper plough layer however, though the longevity of such changes varies. Soils that ordinarily are under reduced or zero tillage management sometimes require conventional tillage to counter natural increases in soil bulk density in such systems over time (Dexter, 1988; Ball et al., 1997). Traffic-derived soil loading can be reduced further by increasing the contact area of tyres or using tracked vehicles to reduce contact pressure. Reversing compaction effects through tillage is easier done for light-textured soils, though sandy soils are vulnerable to compaction, compared to heavier-textured soils where the

Fig. 5 Compaction affects the ability of roots to penetrate strong soil layers and can lead to lateral rather than vertical growth, as can be demonstrated in experimentation with rhizotrons.

compaction will have tended to result in plastic deformation of soil. Subsoil compaction is particularly difficult because it is rarely detected and the negative effects can be cumulative, less-easily rectified by agricultural intervention, and costly when rectification is possible (Hu et al., 2021).

Some soils are able to recover soil structure to a greater or lesser extent from compaction. Clay soils, especially those containing expanding clay minerals (e.g., smectite, vermiculite) can recover structure through their ability to shrink and swell in response to drying-wetting or freezing-thawing cycles (Dexter, 1988; Hallett and Bengough, 2013). This has been termed 'self-mulching' and SOM is thought to be involved also (Kay, 1998).

Climate change

Global climates are changing. In the northern latitudes, for instance, the trajectory is for hotter, drier summers and warmer, wetter winters than currently, with an increased occurrence of low frequency-high magnitude events such as heatwaves and intense storms (Young et al., 1998; The Royal Society, 2020). Climate change is sure to impact all soil properties directly or indirectly, and soil structure and SOM are no exception (Fig. 2). Soil structure and SOM are explicitly linked to soil biology and microbiology and their processes will undoubtedly respond to changes in climate (Young et al., 1998). The direction of response however is unknown as our understanding of the effects is still in its infancy. Fuller understanding will depend on further controlled experiments (e.g., Free-Air Carbon dioxide Enrichment (FACE) techniques) and advances in modeling. Below is a summary of some current broad ideas.

Greater warming and atmospheric carbon dioxide (CO_2) concentration may increase microbial activity, resulting in either a net loss of SOM through oxidation, and may increase net primary productivity, resulting in a net gain of SOM from greater inputs of shoot- and root-derived residues to the soil. It has been suggested that plant material growing under elevated atmospheric CO_2 conditions may shift in its chemical composition (Young et al., 1998). This could have implications for the turnover of SOM if the lability of the plant-derived residues changes. In addition, there could be changes in the allocation of photosynthate, with evidence suggesting a greater proportion of C being allocated to the roots, with greater turnover of roots as a result (Young et al., 1998). Some models predict significant loss of SOM while others suggest seasonal patterns of decreased respiration during the

growing season and increased respiration in the non-growing season, based largely on the effects of predicted environmental changes in temperature, moisture and CO₂ on plant growth and microbiological processes.

Structure stability will likely degrade if those instance where SOM declines. Organic peat soils can suffer irreversible shrinkage upon drying. Prolonged drying can increase soil hydrophobicity and soil strength. If climate change affects patterns of wetting and drying, then these will impact on soil structure and SOM. In general, rewetting events tend to encourage bursts of microbial activity, which can alter soil structure and expose SOM to oxidation (Young et al., 1998). During periods of intense rainfall, leaching of polyvalent cations such as calcium (Ca) and magnesium (Mg), which play a role in soil structure development and stabilization, may create a more acidic soil susceptible to dispersion (Young et al., 1998). Sea level rise could degrade soil structure in coastal soils where inundation of sea water would be an increased threat due to increased salinity which commonly reduces aggregate stability. Excessive accumulation of soluble salts can affect soil microorganisms with implications for SOM. Increased incidence of wildfires can have degrading effects on SOM as it is thermally oxidized, with effects on soil structure as a result (Ferreira et al., 2022), and likely increases in soil hydrophobicity with implications for soil water dynamics.

Effects of soil structure and SOM degradation on soil functions

Soil structure and SOM are key controls on the ability of soil to carry out its functions in support of wider ecosystem services. The effect of degradation of soil structure and SOM on four principal types of function or service are discussed below: net primary productivity; regulation of water and air; biodiversity support; and climate change mitigation (Fig. 1).

Net primary productivity

In many cases the primary function that a soil carries out is to support vegetation, ranging from climax vegetation in natural ecosystems, to extensively-managed vegetation in semi-natural systems, to intensively-managed crops in agricultural systems. The key parameter of this function is the net primary productivity of the system, including the yield of food and fiber. These are severely affected by soil structure and SOM degradation (Ferreira et al., 2022; The Royal Society, 2020) (Fig. 6).

Degradation of soil structure affects plant growth through increased soil strength, retarded root growth, reduced aeration, increased waterlogging, and a decrease in soil friability (Ball et al., 1997). Crop growth is significantly challenged where soil strength exceeds 2 MPa (Hallett and Bengough, 2013). Degradation arising from tillage can destroy biopores created by earthworms and similar soil engineers, which are often the pores that plant roots use preferentially (Dexter, 1988; Or et al., 2021). Plant productivity is decreased due to effects on decreased soil exploration and soil resource capture by the roots. Excessive water retention arising from degraded soil structure can create anaerobic conditions known to retard root elongation. Crop growth is affected where the macroporosity, or air-filled porosity is less than 10% by volume (Dexter, 1988). Ponding at the soil surface from a compacted soil structure reduces infiltration and vertical hydraulic conductivity and can affect the ability to carry out farm operations in spring on agricultural soils. Erosion on grasslands can have severe effects locally on growth and silage quality. Yields are affected more by soil structure degradation in wetter years, perhaps through waterlogging at key growth stages, compared to drier years (Ball et al., 1997; Hu et al., 2021), although the reverse is more likely to be the case when the strength of soil increases significantly as it dries.

Soil structure degradation can reduce microbial functions. Compaction-induced structural degradation has been associated with a reduction in N mineralization. Denitrification and ammonia (NH₃) volatilization can increase with compaction-induced structural degradation (Ball et al., 1997). Similarly, phosphorus (P) and potassium (K) nutrient uptake rates are reduced in structurally-degraded soils that become waterlogged and C can be lost in dissolved forms, whereas concentrations of other elements and compounds, such as ethylene (C₂H₄) and manganese (Mn), can increase to toxic levels. Soil structural degradation can also increase the susceptibility of a crop to soil-borne diseases and fungi.

Degradation of SOM affects food, fiber and productivity, and any such reduction in these functions has a feedback effect in reducing the amount of plant residues returned to the soil which form SOM. Soil erosion leads to the loss of topsoil and its components of nutrients and SOM, which reduces productivity and yield (The Royal Society, 2020). Degradation of SOM has concomitant effects on supporting plant growth through its effects on plant nutrients. Loss of SOM can reduce the exchange of important nutrients such as N, P, and sulfur (S) (Johnston et al., 2009).

Net primary productivity	Regulation of water and air	Biodiversity support	Climate change mitigation
• reduced growth and yield • reduced plant residue return	• waterlogging and anaerobism • surface runoff and flooding	• reduced habitat space and food • reduced biodiversity	• loss of soil carbon • emission of greenhouse gases

Fig. 6 A summary of the main effects of interactive degradation of soil structure and soil organic matter on soil functions and ecosystem services.

Regulation of water and air

Soil structure degradation has important repercussions for the regulation of water and air (Fig. 6). The propensity for compaction to reduce macroporosity decreases infiltration rates. Compaction preferentially affects macropores and can change the alignment of pores from vertical to parallel with respect to the soil surface. Vertical hydraulic conductivity is severely compromised as a result (The Royal Society, 2020). This increases the risk of surface runoff, through both infiltration-excess and saturation-excess means, and subsequent erosion, loss of topsoil, flooding and pollution of water courses (Ball et al., 1997; The Royal Society, 2020). This is particularly important for surface-applied agrichemicals which can lead to eutrophication of freshwaters through the loss of N and P, and movement of sorbed herbicides and pesticides in eroded soil. Some biopores can be resistant to compaction-induced soil structural degradation however. Biopores created by growing roots and burrowing earthworms tend to have walls strengthened by organic residues and clay particles aligned to the direction of root growth or earthworm movement, making them particularly stabilized. Wider environmental problems can arise from flooding, including the silting of water courses from eroded soil, damage to buildings and infrastructure, and the loss of life (Hu et al., 2021; Ferreira et al., 2022). Tillage can remove surface residues leading to loss of soil water through evaporation.

In the soil, soil structural degradation can increase the potential for waterlogging and reduced aeration (Ball et al., 1997). In the most extreme cases this can cause anaerobic conditions to develop in the soil. Small changes in air-filled porosity can have large effects on diffusivity and air permeability. Storage and transport of heat in soils is also affected. Conversely there have been instances of increases in preferential flow with compaction. Drying of the topsoil can occur where root penetration is impaired, and roots are concentrated in the upper layers. The loss of SOM reduces the amount of water retained by the soil, although the magnitude of this may be small and is inevitably soil-specific (Minasny and McBratney, 2018). A corresponding reduction in the sorption capacity of soils with SOM loss would be expected, which could impact on the ability of soils to retain nutrients and agrichemicals.

Biodiversity support

Soil-dependent biodiversity is dependent on habitat space and a supply of organic material. It follows therefore that degradation of soil structure and SOM, respectively, will adversely affect biodiversity (Huber et al., 2008) (Fig. 6), although the full soil structure-SOM-biology interaction remains little-understood.

The soil pore network component of soil structure provides the habitat for soil biodiversity. It is important that soil has a diversity of soil structural components, providing a variety of habitats and niches, as this tends to lead to increased biodiversity (The Royal Society, 2020). Processes that degrade soil structure by removing larger pores, such as compaction, tends to adversely affect macrofauna such as springtail (Collembola), arthropods (Arthropoda), potworms (Enchytraeidae), and both surface-dwelling and deep-burrowing earthworm species (Gregory et al., 2015; The Royal Society, 2020). Earthworms are linked to productivity and yield. Termites and ants may be affected by soil structure and SOM degradation, but their influence tends to be highly localized around social nests compared to the dispersed populations of non-social earthworms. Soil structural degradation can reduce soil-pupating larvae. Effects on butterflies and moths (Lepidoptera) and some bird species have been noted, presumably due to the effect on soil-dwelling prey (Gregory et al., 2015).

The quantity and quality of SOM, as the primary food source, largely controls the soil microbial biomass and can also control biodiversity. Studies following land-use change between annual arable cropping and perennial grass systems have shown rapid changes in the soil microbiology, including increases in fungal populations and the mesofauna in the latter (Hirsch et al., 2017), although bacterial diversity is unaffected (Hirsch et al., 2009). Studies have reported that increased quantity of SOM can increase populations of larger detritivores (anecic earthworms) and decrease smaller groups (springtail), and that low-quality recalcitrant SOM is linked to increases in the relative proportion of fungi and fungal-feeding nematodes (Nematoda) (Sauvadet et al., 2016). SOM has been positively correlated with the abundance of flies (Diptera) and aerially-active beetles (Coleoptera) in arable soils (Gregory et al., 2015). Lower fungal biomass and fungal-to-bacterial biomass ratios have been found in soils of smaller SOM content compared with undisturbed SOM-rich soils. Fungi are particularly affected by soil structure degradation (e.g., especially tillage operations) and a change in land use can decrease SOM (Tisdall and Oades, 1982).

Climate change mitigation

Soils have a crucial role to play to help mitigate climate change through its part in the global C cycle. Soils contains more C globally than the atmosphere and vegetation combined. Small changes in C fluxes can have a great effect on the global C cycle therefore. Degradation of SOM causes a release of C from the soil to the wider environment—most commonly to the atmosphere. Soils could flip between being a sink and a source of C if degradation occurs (Fig. 6). Principle examples of where a soil may change from C sink to C source include losses of SOM from cultivation of semi-natural land, urbanization, drainage of naturally humid soils (e.g., peatlands and fenlands), and peat extraction (Cannell et al., 1999).

Soil structure degradation can exacerbate problems. Emissions of methane (CH_4) can occur under low-oxygen conditions when SOM is degraded by methanogenic bacterial microorganisms that excrete it as a by-product (The Royal Society, 2020). Similarly, emissions of nitrous oxide (N_2O) occur under anaerobic conditions, in the presence of nitrate (NO_3^-) and available C, when denitrification occurs (Ball et al., 1997; Hu et al., 2021). As CH_4 and N_2O are significantly more potent greenhouse gases than CO_2 (approximately 30 and 300 times the global warming potential of CO_2 , respectively), this can seriously compromise the ability

of soils to mitigate climate change. Erosion of SOM-containing topsoil can release previously-protected C to the atmosphere (Ferreira et al., 2022).

Other soil functions and ecosystem services

In addition to the four principal areas discussed above, degradation of soil structure and SOM can impact on other soil functions and ecosystem services.

SOM plays a key role in the ability of soils to buffer the effects of potentially-toxic substances, in part by chelation and adsorption (Ferreira et al., 2022). Loss of SOM can reverse this and release toxic elements. Waterlogging following structural degradation causes reducing conditions in soils which can impact on buffering and contaminant filtering. This can affect the quality of drinking water supplies and can lead to eutrophication problems in freshwaters.

Soils are the foundation for many amenity uses of land, such as for sport and recreation. Many amenity uses are reliant on a healthy resilient vegetative covering, such as turf. It is apparent therefore that degradation of soil structure and SOM has a negative impact on the function of soils to support most amenity uses through effects on quality of turf and the ability of the ground to resist stresses. There are some minor exceptions to this, such as the deliberate degradation of soil structure by compaction for the sport of cricket. Soils are also the repository of cultural heritage. Soil structural degradation can negatively affect the preservation of cultural artifacts and archeology in the soil. However, whether waterlogging following structural degradation preserves or degrades archeological materials in soils is not clear.

Soils have an important function as a support for the built environment and infrastructure. This is an example of a function that is often dependent on deliberately degrading soil structure and SOM to create a compacted inert foundation for building or engineering works. Nevertheless, changes in soil structure such as shrinking can adversely affect soils as building foundations (Young et al., 1998).

Summary and outlook

Soil structure and SOM have an interactive relationship and hence it is demonstrably the case that a degradation on one will impact the other. This article has sought to summarize the key processes and mechanisms by which soil structure and SOM can be degraded. Some of those processes and mechanisms are natural, such as those associated with natural pedological soil-forming factors, including the stresses imparted by the ordinary climatic conditions under which a soil is subjected. However, it is the case that many of the ways in which soil structure and SOM are degraded are as a direct or indirect result of management interventions. Management, particularly in agriculture, controls surface vegetation, inputs of organic residues from vegetation, livestock and amendments, and soil physical conditions through tillage and traffic-induced compaction. All of these impact on soil structure and SOM. Subsequently these have implications for soil functions and ecosystem services that are reliant on soil structure and SOM, including net primary productivity, regulation of water and air, and biodiversity support. Potentially mitigating, but most likely aggravating, the degradation of soil structure and SOM is the changing climate, which itself is affected by the dynamics of soil structure and SOM.

The positive message is that we have as a foundation a basic theoretical fundamental understanding of what causes the degradation of soil structure and SOM, and how it affects the functions and services we ask of soils. There is the caveat that soils are arguably the most complex systems on the planet with huge natural variation in characteristics, which makes their study and understanding equally challenging but compelling. Generalizations often have to be adapted to local conditions. Nevertheless, there are broad management interventions that ought to slow or reverse degradation of soil structure and SOM. We can modify agricultural practices to prevent or minimize SOM degradation, including use of crop rotations, grass leys, perennials, cover cropping, agroforestry, and organic amendments. We can reduce soil structure degradation by minimizing tillage, reducing traffic tyre or track pressures, using controlled traffic systems, reducing livestock density, and reducing soil stresses at particularly vulnerable times, to reduce soil compaction. Reversals of previous soil structure and SOM degradation may be achieved through addition of organic amendments and careful soil engineering. Seemingly small changes in SOM may be manifest in disproportionate great effects on soil structure-controlled properties and functions, because certain SOM components, such as particulates and polysaccharides, are likely more important than total SOM per se.

We can still improve our knowledge of the fundamental soil structure-SOM interaction, how this is controlled by management, and the subsequent effects on soil functions and ecosystem services. Future research will be able to exploit developing technologies and methodologies. These include the great advances that have been made in the non-destructive characterization of soil structure (see Non-invasive imaging of soil processes) and physical, biological, and chemical characterization of SOM (see Spectroscopic Methods (FTIR, Diffuse Reflectance Spectroscopies)) together with the greater power of mechanistic modeling to predict future trajectories.

Abstract

Drainage is the natural or artificial removal of water from the land either through surface drainage, subsurface drainage or a combination of both. The practice of land drainage may be beneficial if soil water conditions create a need for drainage due to shallow groundwater or soils with low permeability. In agricultural settings, the natural, internal drainage of most soils is adequate to prevent waterlogging, but many soils require artificial drainage to improve field trafficability for field operations and to protect growing crops from excess soil water conditions. Drainage helps to provide an optimal balance of water and air in the soil necessary for plant growth, as well as the diverse function and services of soil-dwelling organisms.

Key points

- Artificial drainage mitigates risk and damage to crop production from excess soil water conditions.
- Drainage provides optimal conditions for growing plants and soil organisms.
- Drainage system planning, design, installation, operation, and maintenance are critical for success.

Introduction

Drainage is a natural process and is a component of the global hydrologic cycle whereby water moves across, in, through, and out of the soil as a result of various forces. Historically, land drainage might be undertaken for one or more of the following reasons: improvement of the agricultural potential of soils; the reclamation of wet soils to improve the stability of roads and building sites; or for health reasons, to reduce the potential for malaria or other infectious diseases. According to the International Commission on Irrigation and Drainage (ICID, 2017), the global land area estimated to be artificially drained is about 194 Mha. Drainage of the soil

* Retired.

can be accelerated by the use of surface and subsurface drainage practices. Soils that require accelerated drainage typically have some impermeable or slowly permeable feature at or below the soil surface that either limits water from entering the soil or after the water has entered the soil and restricts its movement deeper into the soil and underlying materials at a rate that allows efficient and economical use of the water resource.

Drainage systems permit or improve crop growth and production through removal of non-capillary water from the soil profile. The essential functions of these drainage systems are to prevent flooding through the rapid removal of surface and non-capillary soil water, lower shallow water tables to prevent crop stress, and create suitable conditions for field operations such as tillage, fertilization, application of crop protection products, and harvest. Wet soils can also delay planting, which has a direct negative effect on yield potential due to a reduction in growing degree days. In addition, plant and root diseases are more common in wet, poorly drained soils and plants may be more susceptible to diseases in these stressful growing conditions (Strock, 2018).

The importance of proper drainage and drainage system management are critical for crop production on naturally poorly drained soils in humid and sub-humid regions affecting millions of hectares. In addition, drainage has direct and indirect effects on the provision of ecosystem services including impacts on soil organic carbon (SOC) stocks, organisms living in the soil, nutrient cycling, water retention on the landscape, groundwater recharge, greenhouse gas (GHG) emissions, nutrient losses to surface and groundwater, riparian vegetation, wildlife habitat, and the resilience of cropping systems to climate change.

Climate change

There is an increasing body of evidence that supports the proposition that climate change will impact ecosystems, communities, and human livelihood (Meerhoff et al., 2022; IPCC, 2013; Kumar et al., 2014; Parmesan and Yohe, 2003; Patz et al., 2005; Wheeler and von Braun, 2013). Two commonly ascribed effects of climate change are increasing temperature and extreme weather variability. Anticipated changes in the frequency and intensity of extreme events (e.g. droughts, heatwaves, severe storms, extreme rains) may also affect ecosystem stability and resilience (García-Palacios et al., 2018; Pimm et al., 2019). Hydrologic and thermal effects of projected climate change will have direct and indirect consequences for freshwater ecosystems, for example, human water use, increased incidence of flooding and low flows, the rate of growth and distribution of freshwater organisms, and impacts on water quality (van Vliet et al., 2013).

Temperature

Temperature is an important environmental factor that effects physical, chemical and biological properties and processes in aquatic ecosystems. Water temperature can affect chemical (e.g., dissolved oxygen concentration) and biological (e.g., decomposition, growth rate of aquatic organisms) processes occurring in a water body. Water temperature fluctuations can occur naturally or as a result of human disturbances such as thermal pollution, riparian vegetation removal (e.g. deforestation), and climate change.

One of the earliest responses to climate change is expected to be alterations in river and lake water temperature. Factors influencing the thermal regime of surface waters can generally be classified into four groups: (1) atmospheric conditions (e.g. solar radiation, air temperature); (2) topography (e.g. latitude/altitude, shading); (3) streambed (e.g. geothermal conduction, groundwater input); and (4) stream discharge (e.g. inflow/outflow) (Caissie, 2006). Stream discharge, mostly a function of water hydraulics (e.g. inflows and outflows), mainly influences the heating capacity (volume of water) and or cooling through mixing of water from different sources including influx of precipitation, surface runoff, subsurface drainage, and groundwater.

Precipitation

The need for drainage can vary within a growing season due to seasonal climate patterns and differences in crop tolerance to excess water throughout the growing season. Climate projection models predict that, in the future, areas with high precipitation will become even wetter, especially in the Northern Hemisphere (Holopainen et al., 2016; IPCC, 2019). Changing precipitation patterns will complicate the effects of agricultural subsurface drainage, particularly in regions where the frequency and magnitude of heavy rain events are increasing relative to average precipitation (IPCC, 2013). Projected increases in precipitation patterns under future climate scenarios will probably increase surface runoff and subsurface drainage, making water management more challenging. It is likely that more frequent, intense and higher amounts of precipitation will increase nutrient loss from agricultural land and affect non-point source pollution thereby increasing nutrient concentrations in receiving water bodies. Nutrient exports from agricultural watersheds are mainly attributed to surface and subsurface drainage networks that promote rapid drainage, but also to the relatively large inputs these watersheds receive from fertilizer and livestock manures. Subsequently, as water temperature and nutrient concentrations increase, algal growth is expected to be stimulated, leading to water eutrophication and algal blooms. Consequently, eutrophication will be accelerated due to the increased nutrient supply, higher temperatures, and greater net primary production.

Soil hydrology

Precipitation, as well as irrigation, delivers water to the land surface. The frequency, intensity, duration, rate, and amount of precipitation and the properties of the soil determine the relative amounts of water that will infiltrate, runoff, or remain on the soil surface temporarily as surface water storage. Water that runs off does so by the natural process of surface drainage, sometimes called runoff or overland flow. The water that remains temporarily stored on the surface will eventually either evaporate or infiltrate into the soil matrix. Water that infiltrates into the soil increases the soil water content and may ultimately be evaporated back to the atmosphere directly, be taken up by plants, or move deeper into the soil where it could then undergo lateral flow and move beyond the area of infiltration.

The forces of cohesion, adhesion, and gravity control the redistribution of water that infiltrates into the soil. Water infiltrates into a network of pores within and between soil particles and structural aggregates and adheres to these components. Additional soil water accumulates as water coheres to water already in contact with the soil particles. Within small pores, enough water can be held against the force of gravity to fill the pores completely. Pores that hold water against the force of gravity are called capillary-size pores. In larger pores, all of the water that enters cannot be held against the force of gravity and some of the water moves downward through the soil in these pores. This process is called percolation; percolation is a natural drainage process. Water that percolates deeper into the soil may: enter capillary-size pores at greater depths and increase the soil-water content; encounter restrictive features that block its descent and cause accumulation of water in the form of a perched water table; reach and add to an existing water table; and or reach and replenish an aquifer.

Drainage

Land drainage can be accomplished by surface drainage, subsurface drainage or a combination of both systems.

Surface drainage

Surface drainage diverts excess water from the soil surface directly to streams, thereby reducing the amount of water that will move into and possibly through the soil. Surface drainage is accomplished by land forming, grading, or smoothing to remove small depressions where water collects and to provide a uniform slope for the removal of surface water. The orientation of the graded land and thus direction of surface drainage is normally toward an adjacent open drain (ditch). If the ditch is sufficiently deep it will also receive water transported laterally through the soil profile. A field is considered to have good surface drainage if it has a small amount of depressional storage that must be satisfied before surface drainage occurs. In contrast, poor surface drainage is characterized by a large amount of depressional storage that must be satisfied before surface drainage can occur. Water management by means of surface drainage enhances overland runoff and thus requires less intensive subsurface drainage than would be needed if surface drainage were poor. The main concerns regarding surface drainage are increases in rates of peak flow in receiving waters, loss of wetlands, increased loss of sediment and sediment-bound nutrients, and the loss of other pollutants found in surface runoff, such as pesticides and bacteria.

Subsurface drainage

Subsurface drainage describes the process of removal of that water which has infiltrated into the soil in excess of the amount that can be held by capillary forces against the force of gravity. The goal of subsurface drainage systems is to remove non-capillary water from the upper layers of the soil profile as quickly as possible to ensure an adequately aerated root zone and trafficability for critical field operations such as planting and harvesting. Subsurface drainage systems to manage shallow water tables are designed to remove excess pore water from the soil profile to a specific design depth, typically between 60 and 120 cm. Excess pore water is defined as moisture contents greater than field capacity, defined as pressures less than 10-kPa tension for coarse textured soils and 33-kPa tension for fine textured soils. When soil moisture exceeds field capacity, or when the water table rises above the drain depth, soil water from larger pores can move to subsurface drainpipes or ditches. Subsurface drainage, provided by ditches and drainpipes (aka 'tile'), collects and diverts non-capillary water from within the soil directly to ditches, or streams and rivers. Buried drainpipes may be constructed of clay, concrete, or perforated, corrugated polyethylene pipe. Drainpipes act as conduits that transmit water through their walls and can be placed at a range of depths and spacing's in the soil. By connecting ditches and buried drainpipes, subsurface drainage systems can be created to remove non-capillary water from broad areas of soil.

Design, installation, and operation of subsurface drainage systems require thorough planning and consideration of factors including: climate, crop requirements, soil properties, and site characteristics (Strock et al., 2011). It is widely accepted that some crops are more tolerant of poorly drained, wet conditions than others. Water management for most crop production is important during the growing season. As drainage pertains to climate, it is conceivable that there are times during the growing season when an entire rainfall will infiltrate into the soil. At other times, when rainfall is frequent and intense, the soil may become saturated with water and it may be necessary to remove excess water within 24 h in order to minimize crop damage. There may also be times when

Fig. 1 Schematic diagram of the conceptual drainage system design patterns (A) Random, (B) Parallel, and (C) Herringbone.

the intensity of rainfall exceeds the infiltration capacity of the soil and water is forced to run off the soil surface. Subsurface drainage systems to manage shallow water tables consists of two distinctly different types: conventional free drainage and controlled drainage.

Conventional free drainage

Subsurface drainage systems are commonly installed in either a random, parallel, or herringbone pattern (Fig. 1). A random design may be used where field topography is rolling in order to remove excess water from wet areas in a field. In the case of the random pattern, a single tile drain may be installed through several isolated depressions. A parallel drainage system consists of lateral tiles that are oriented perpendicular to a main field tile drain to drain an entire field. The herringbone configuration consists of lateral drain tiles, oriented in a diagonal manner, entering a main drain from both sides.

Design, installation, and operation of a subsurface drainage system requires thorough planning and consideration of many factors including: soil properties, climate, crop, economic, and environmental factors. The risks of excess water on crop production and profitability depend on these factors. To a great extent drainage design, installation and operation are site-specific activities. Subsurface drainage design is a process of selecting drainage depth, spacing, and layout to mitigate the negative consequences associated with excess water in the soil profile, while balancing the costs associated with the drainage system (Sands, 2003). The ultimate choices of drain depth, spacing, and layout have to be considered to optimize drainage system design where net returns on investment (benefits minus the costs of the system) are maximized over the life of the system.

The proper depth and spacing of subsurface drains depend on multiple factors including site conditions, management factors, and soil characteristics. It is not within the scope of this chapter to describe fully drainage system planning, design and installation, however, there are resources readily available to aid in the process (e.g. Smedema et al., 2004). Briefly, drain depth and spacing should be determined such that the drainage system can reduce the depth of the water table between the drain lines to an elevation that is most beneficial to plant growth within 24–48 h after a rain. Subsurface drain pipes come in various diameters ranging from 5 to 60 cm in diameter. These drains are usually installed at depths of 0.6 to 1.5 m deep. Drain spacing for parallel drains can be determined empirically for a given soil using the Hooghoudt equation (Eq. 1) as described by van der Ploeg et al. (1999):

$$L = \left[\frac{8K_2md_o + 4K_1m^2}{R} \right]^{1/2}, \quad (1)$$

where L is the distance between drain lines, R is the design drainage rate, K_1 and K_2 are the hydraulic conductivities of the soil layers above and below the drain, respectively, m is the midpoint water table elevation above the drain tile, and d_o is the effective depth to the impermeable layer. The use of Eq. (1) begins with selecting a drainage rate, R , for a specific site based on soil, crop, climate, and other factors. Design drainage rates can be found in Framji et al. (1987). Typically, drainage rates range from 6 to 40 mm^d. Once the design drainage rate and drainage depth are selected, drain spacing can be determined solving Eq. (1) for L .

Although all of the potential combinations of site conditions, management factors, and soil characteristics cannot be adequately described in the context of this chapter, in general, as soil texture becomes finer (i.e. clay content increases) it may be necessary to

Fig. 2 Schematic diagram of the conventional free drainage and controlled drainage concepts, using an in-field water control structure.

install drain pipes closer together. In contrast, as the soil texture becomes coarser (i.e. clay content decreases) drain spacing may become wider.

Controlled drainage

The previous section focused on conventional free drainage where the drainage system is managed so that the water table is effectively lowered to the depth of the drainage system outlet. This level of management permits farming under conditions where soils have poor natural drainage and is sufficient to satisfy agricultural production goals. However, in some cases, this level of management may lead to excessive drainage which is undesirable during the growing season since it reduces the amount of plant available soil water and could lead to increased water stress and yield reductions during unusually dry periods. Excessive drainage may also lead to leaching losses of important fertilizer nutrients and other constituents transporting them to surface waters where they may lead to impaired water quality.

Controlled drainage is a practice that has developed for temporarily storing water in the soil profile and reducing nitrogen loss from agricultural fields with subsurface drainage (Skaggs et al., 2010; Helmers et al., 2022). Controlled drainage influences soil hydrology since it can be used to raise a shallow water table, which increases soil wetness in the upper part of the soil profile. Controlled drainage is accomplished through management of the drainage outlet which can be set at any level between the ground surface (undrained) and the drain depth (conventional free drainage) depending on farming needs, precipitation–evapotranspiration conditions, soil water content, and water table elevation (Fig. 2). Raising the outlet elevation of a controlled drainage system effectively reduces overall drainage volume and consequently nutrient loss (Skaggs et al., 2010; Youssef et al., 2018; Helmers et al., 2022).

The suitability of a field for controlled drainage must be considered during the planning and design stages of the drainage project. Landscapes which support the implementation of controlled drainage are normally flat, with slopes less than 0.5%. As slopes approach 1%, the number of control structures required to maintain a shallow water table within the desired management depth increases as does cost. At slopes greater than 1%, drainpipes can be installed following natural topographic contours. Controlled drainage can be used with any drain spacing; however, narrower drain spacing is common in order to maintain a relatively 'flat' shallow water table. Narrow drain spacing also reduces the risk of yield loss due to excess wetness during the growing season because water is removed from the soil at a faster rate. Narrower drain spacing also increase drainage system cost.

To maximize the benefits of controlled drainage, farmers/managers must actively manage the control structures throughout the year. Controlled drainage systems can be managed during the growing season to alleviate plant stresses caused by dry conditions, potentially resulting in higher crop yields. In contrast, if poorly managed, controlled drainage may also have an adverse effect on crop growth and yield during wet growing seasons since it may delay and or reduce the removal of non-capillary soil water in the root zone, contributing to plant stresses due to wet conditions (Youssef et al., 2022). The potentially positive and negative effects of controlled drainage on crop performance depend on the frequency, duration, timing and severity of dry and or wet conditions and how intensively a controlled drainage system is managed in response to these conditions.

The optimization of crop performance by controlled drainage is typically achieved by managing water table depths between 45 and 60 cm from the soil surface, halfway between drainpipes. Management of the drainage system outlet depth will vary depending on factors including drainage system design, soil texture, crop type, and growth stage. Ideal water table depths for coarse textured (e.g. sandy) soils, which are susceptible to dry conditions, should be shallower and closer to 45 cm. In contrast, for fine textured (e.g. clay loam) soils, which would be susceptible to wet conditions, should be managed at 60 cm or deeper.

Environmental effects of drainage

Although many sources, including wastewater treatment plants, domestic septic systems, and urban nonpoint sources contribute water and nutrients to surface waters, agriculture is the foremost source in many areas of the world. Numerous adverse effects of drainage on water quality have been identified; specifically, artificial drainage increases nitrogen and phosphorus loads to

downstream waters (Dinnes et al., 2002; Gentry et al., 2007; Wang and Li, 2019). Some of the adverse effects of drainage are avoidable and some can be minimized by the adoption and implementation of various management practices.

Recognition that artificial drainage contributes to impaired surface waters has led to the development of methods and technology for water table management (Strock et al., 2010), and also practices aimed at addressing the reduction in both nitrogen and phosphorus loads (Baulch et al., 2019; Xia et al., 2020). Loss of nitrate-nitrogen from artificially drained agricultural land has been the focus of numerous research studies. Research has concentrated on factors including precipitation; soil organic matter mineralization; cropping system; timing, source, and rate of nitrogen application; use of nitrification inhibitors and slow-release nitrogen fertilizers; tillage; and drainage system depth and spacing (Randall and Goss, 2008). Nitrate-nitrogen loading has been associated with hypoxia in coastal waters, but recent evidence indicates that phosphorus also plays a critical role (Dodds, 2006; Rabalais and Turner, 2019). Phosphorus loss has been an important water quality issue for decades because of the critical role P plays in eutrophication. Historically, the majority of research on phosphorus losses has focused on surface runoff and erosion because such losses were considered negligible from subsurface drainage. More recently, research has revealed a better understanding of the magnitude and importance of subsurface drainage on dissolved phosphorus transport and loading to surface water (King et al., 2015). Subsurface drainage has been shown to reduce total phosphorus losses because drainage reduces surface erosion and surface runoff which are the main drivers for sediment associated phosphorus export (Wagena and Easton, 2018).

Practices to improve water quality and peak flows

Drainage coupled with climate change has the potential to affect hydrology and diffuse nutrient export from agricultural landscapes. Climate change is causing an increase in the magnitude and frequency of large precipitations events, and longer, more frequent droughts. Increasing flood and drought risk contribute to the need for a robust suite of hydrology and water management practices to support adaptation and mitigation options in the near future. The increase in amount and intensity of precipitation will contribute to greater diffuse nutrient and sediment export from landscapes.

Buffers and filters

Buffers and filter strips have been found to be effective in trapping contaminants, especially particulate pollutants (Dabney et al., 2006). There are numerous terms and definitions for filter strips and riparian buffers including vegetative filter strips, conservation filters, conservation buffers, riparian buffer zone, buffer strips, riparian buffer. Filter strips primarily slow runoff velocities and filter out sediment and other pollutants from surface runoff and erosion. Filter strips can be located anywhere on the landscape and do not need to be adjacent to a surface waterbody. In contrast, riparian buffers must be located adjacent to a surface waterbody such as a lake or river. While there has been extensive use of filter strips and riparian buffers to improve water quality, it is generally not possible to suggest a size for them to meet specific water quality improvement goals due to difficulties with predicting their performance effectiveness (Helmets et al., 2008). The performance of a buffer or riparian system depends on the field, topographic, and climatic conditions at the site. The main constraints to establishing buffer or filter systems are associated with the cost of establishing them and in taking land out of production.

Controlled drainage

Controlled drainage was described in detail in the section ‘Subsurface drainage.’

Cover crops

Row crop agriculture is under scrutiny with the aim to reduce runoff, erosion, and nutrient concentrations and loads in drained agricultural landscapes. The use of cover crops and applying appropriate rates of fertilizer, especially N, for maize (*Zea mays* L.) are potential management strategies to reduce nutrient losses in tile drainage water (Dinnes et al., 2002). Cover crops have the potential to decrease soil erosion and particulate nutrient loss in surface runoff and leaching, however their effectiveness is reduced when germination and stand cover are limited by poor germination, by lack of fall precipitation, or short growing seasons (Strock et al., 2004; Noland et al., 2018).

Wetlands

Natural, restored, and constructed wetlands represent a potentially promising practice for treating agricultural drainage whether the influent consists of surface water runoff, subsurface drainage, or a combination of both. Research has demonstrated that wetlands can provide removal of suspended sediments, biological treatment of nitrogen, and storage of carbon and phosphorus (Kadlec and Knight, 2008; McCarty and Ritchie, 2002). Wetlands are very efficient at removing nitrate. They are also considered effective in removing phosphorus associated with suspended sediment; however, they are less effective in retaining phosphorus than nitrogen. Wetlands are generally considered to be phosphorus sinks due to sediment accumulation of bound inorganic and organic phosphorus.

The effectiveness of wetlands depends on several factors including: climate; temperature; hydraulic loading and residence time; wetland to watershed area ratio; type and density of vegetation; the characteristics of the microbial communities; and the distribution and characteristics (concentration) of the influent water. Optimal reduction in nutrients occurs when hydraulic residence time is long and the rate of hydraulic loading is low. One disadvantage of wetland restoration is that the wetlands often disrupt the continuity of farming practices because of their location, thus the targeted positioning of constructed wetlands to treat agricultural drainage is promising.

Bioreactors

Recently, researchers have evaluated the use of organic fibers, in particular corn cobs and woodchips, etc., for the remediation of nitrate from subsurface drainage (Christianson et al., 2012; Jaynes et al., 2008). Bioreactors are excavated areas (beds) filled with organic fibers through which subsurface drainage waters are directed for treatment. There have been several different designs for denitrifying bioreactors including, in-field denitrification walls (Jaynes et al., 2008), edge-of-field bioreactors (Woli et al., 2010) and stream bed bioreactors (Robertson and Merkley, 2009). With sufficient hydraulic retention time in the bioreactor, denitrification is enhanced and nitrate loads are reduced in bioreactor effluent. The organic fibers act as a carbon source for microorganisms to convert NO_3^- to N_2O and N_2 gases through denitrification. The state of bioreactor science has been well summarized by Christianson and Schipper (2016).

Saturated buffers

Saturated buffers are a conservation practice that diverts subsurface tile drainage into riparian soils through a network of distribution pipes that effectively slow the discharge of agricultural drainage water to waterways while simultaneously extracting nutrients. Subsurface drainage is diverted by a water level control structure to a series of perforated drainpipes that run parallel to a ditch or stream. Drainage water seeps through the soil beneath the riparian buffer, artificially raising the water table between the drainpipes and the ditch. Recent research concluded that when proper site conditions and design considerations are met, saturated buffers can be an effective method for reducing nitrate transport from subsurface drainage systems (Utt et al., 2015).

Drainage water recycling

Drainage water recycling comprises a water storage reservoir linked to an in-field subsurface drainage system. Excess water is drained from the field and is subsequently stored in the reservoir to be recycled as irrigation water, either through surface or subsurface irrigation systems. This practice is most effective in fields with relatively dense drainage (i.e., narrow drain spacing). Benefits of drainage water recycling include the diversion of nutrients (e.g., nitrogen and phosphorus), and other contaminants (e.g., sediment) away from downstream waters (Frankenberger et al., 2017). In addition, reservoir storage can potentially buffer peak flows. Drainage water recycling has been shown to increase crop yields (12–19%), and with even greater increases (25–29%) under moderate drought conditions (Frankenberger et al., 2017; Baker et al., 2012). Reservoir construction, however, results in a loss of farm revenue because of taking land out of production but improved yields on the remaining acreage may mitigate those losses.

Water storage

Increasing or restoring water storage in the landscape can help reduce nutrient export from watersheds (Wilson et al., 2019). In addition, water storage practices can be implemented to achieve reductions in flow and associated channel erosion. Water storage practices are those that have the ability to mitigate water flow in terrestrial and aquatic environments (Rhees et al., 2022). Examples of potential water storage practices used in the USA are listed in Table 1. Water storage practices can impact water transport through retention or detention, or by affecting components of the hydrologic cycle (e.g., evapotranspiration). Before adoption and establishment of water storage practice, the following key factors should be considered including site suitability, water storage volume, co-benefits (e.g. multiple ecosystem services), limitations (e.g., legal, physical, regulatory, financial, or social constraints), and cost.

Conclusion and outlook

Agricultural drainage has enabled vast areas of marginally productive soils to become highly productive. Adequate surface drainage together with good subsurface drainage can effectively protect crops from excessive soil water conditions. Improving drainage of poorly drained soils improves trafficability and eliminates periods of excess water during the growing season that may result in delayed planting and harvest, and impair crop growth and limit yield potential.

We highlighted management practices and common conservation practices that farmers, land managers, and conservation professionals currently use to decrease agriculture's impact on water quality.

Controlled drainage is a practice that has long been recognized as an effective best management practice for mitigating the effects of agricultural drainage on water quality, especially related to nitrogen. In addition, benefits of water conservation and of higher

Table 1 Examples of water storage practices for reducing flow and nutrient export.

Practice	Description
Pond (NRCS Practice Code 378)	Used to reduce peak flows, prevent erosion, and treat runoff from agricultural and urban lands.
Controlled Drainage (NRCS Practice Code 554)	Uses a control structure to temporarily detain and store soil water in fields with tile drainage systems.
Wetlands (NRCS Practice Codes 656 and 657)	Used to store water through retention and evapotranspiration.
Off-channel impoundments (NRCS Practice Code 362)	Used to divert water from a water course to a storage area using levees or embankments.
Drainage Water Recycling (NRCS Practice Codes 436 and 443)	Used to retain surface and subsurface drainage water in a reservoir to be recycled as irrigation water, either through a surface or subsurface irrigation system.
Ditch and Culvert Improvements	Used to make structural modifications that allow management (i.e., slow) the flow of water.
Riparian Restoration (NRCS Practice Codes 390 and 391)	Used to restore ecological and hydrological conditions to a natural regime adjacent to a stream channel.
Floodplain Connection	Used to reconnect a modified or disconnected channel with its existing floodplain to allow for inundation during higher flow conditions.

crop yields may be attainable when controlled drainage systems are properly managed. Active management of controlled drainage structures is critical for achieving higher yields.

There are emerging issues related to the effects of climate change on precipitation and the emphasis on soil health, sustainability, and resilience. Future attention needs to be directed toward the adoption and implementation of technology (e.g. wireless communication, sensors, artificial intelligence, machine learning, and informatics) for managing, modeling, and monitoring drainage systems focused on productivity, economics, and environmental quality.

Abstract

The chapter describes the importance of irrigated agriculture, the major water consumer, and reviews the effects of irrigation on the availability as well as the quality of land and water resources. Moreover, it underlines the problems related to current irrigation practices, such as pollutants attributable to irrigation, public health concerns as well as socio-economic and policy issues. Finally, it outlines options for improving the environmental performance of irrigation while increasing water productivity in irrigated agriculture. These are complementary goals which are also important for the long-term sustainability of irrigated agriculture.

Key points

- The earliest archeological evidence of irrigation in agriculture dates back to about 6000 BCE.
- Crop yields under irrigation can be increased by 100 to 500% compared with those under rainfed conditions.
- Globally, irrigated agriculture uses the highest portion (72%) of the world's water resources, with a low water use efficiency and productivity.
- Overexploitation of water resources and excessive water usage in irrigation cause water shortages, changes in flow regimes of rivers, rising water tables, triggers drainage and salinity problems.
- Excess water application and particularly surface irrigation methods promote runoff and deep percolation which carry pesticides and fertilizers together with microorganisms and pathogens into rivers, lakes and aquifers.
- Inappropriate wastewater and irrigation practices can have harmful health effects including cholera, typhoid, ascariasis, amebiasis, giardiasis, and entero-invasive *Escherichia coli*.

Introduction

The delta plains of the Euphrates and the Tigris rivers in Mesopotamia, and the Nile in Egypt have witnessed numerous civilizations. Archeological remains of irrigation structures such as barrages, channels, and deep wells date back to as early as 4000–6000 BCE. The real advancement in irrigated agriculture, however, started in the twentieth century with the development of large irrigation projects in Egypt, Pakistan, India, and the USA. Irrigation contributed significantly to the large crop yields achieved following the Green Revolution in the 1960s, which is commonly attributed to the breeding of high-yielding crop cultivars, and use of fertilizers and pesticides.

Irrigation development projects facilitate the improvement of infrastructure such as: roads, telecommunications and energy networks; improvement of public services in health care and education; promotion of investments in agribusiness and related areas; and creation of new employment opportunities. While country-wide prices of agricultural produce tend to decrease under irrigated agriculture, the living standards of the whole population tend to improve; hence the above improvements may lead to substantial

socio-economic development. Irrigated agriculture was also key to alleviating poverty in Asian countries, and its continuing expansion has been considered essential in meeting the needs of increasing populations in the developing world.

The replenishment of water in the plant root zone during periods when natural rainfall is insufficient for good plant growth is the classic definition of irrigation. Irrigation is essential to ensure high crop yields in arid and semiarid regions. Supplementary irrigation in humid and sub-humid regions not only guarantees high crop yields, but also improves the quality of those crops. It is well documented that crop yields under irrigation increase by 100 to 500% compared with yields obtained under rainfed conditions in arid regions as well as globally (e.g. Jaramillo et al., 2020). Irrigated areas increased from a mere 63 Mha in 1900 to 111 Mha in 1950 and to 339 Mha in 2018. Fig. 1 shows the expansion of irrigated areas since 1960 and compares it with the global increases in population and cereal production. Prior to 1950, the areas equipped for irrigation gradually increased (Siebert et al., 2015) and the rate of expansion was 2.2% annually until the late 1970s. The rate of expansion then leveled off to around 1% per year in the 2000s. Although irrigated agriculture is practiced on nearly all continents, 70% of the globally irrigated areas are in Asia, particularly in Pakistan, China and India. For example, an area of about 16 Mha produces more than 90% of the entire agricultural and livestock production in Pakistan (see Sobia et al., 2018 in Qureshi, 2020).

Production of major broad acre crops (wheat (*Triticum aestivum* L.), maize (*Zea mays* L.), rice (*Oryza sativa* L.) and soybean (*Glycine max* (L.) Merrill) shows a strong association with the increasing acreage of irrigated areas (Fig. 1). Although only approximately 25% of the world's arable land is under irrigation, it accounts for more than 60% of the cereal production worldwide and 50% of the sales value of all crops harvested come from irrigated agriculture (Angelakis et al., 2020). Although around 30% only of the world's cereal-planted area is under irrigation, 42% of global cereal production originates from these areas. Eliminating irrigation would reduce cereal production by 20% (see Siebert and Döll, 2010 in Siebert et al., 2015). Based on a 'business-as-usual' scenario, the Food and Agriculture Organization of the United Nations (FAO) estimates that the world will need about 60% more food by 2050, and that irrigated food production will increase by more than 50% over the same period (FAO, 2017). The necessary amount of water, however, is not available: the FAO recognizes that the amount of water withdrawn by agriculture can only realistically increase by 10% (UN, 2021).

In the future, the largest expansion of irrigated areas will take place in Eastern and Near-East countries and in North Africa where farmland is limited and irrigation is the only means of increasing agricultural production. However, for Sub-Saharan Africa and particularly for the developed countries only a marginal expansion of the irrigated area is projected until 2050. An estimated three-quarters of the farmland in East and Near-East countries and North Africa will have irrigation projects implemented in the near future. Similarly, irrigated agriculture will extend to more than 90% of cultivable land in South Asia. However the projected net increase, with an annual growth rate of 0.24% in irrigated land, is much lower than that achieved during the last 50 years (FAO, 2011). The major constraints to the expansion of irrigated areas are the scarcity of land and water resources, increased demand for municipal and industrial water allocations that are in competition with agriculture as well as the rising costs of irrigation project investments.

The expansion of irrigated areas is unsustainable, however, without proper drainage and funding for the appropriate implementation of technical and socioeconomic aspects. History has witnessed the disappearance of numerous civilizations not only because of wars and long spells of drought or floods, but also as a result of the unintended consequences of irrigated agriculture. The Babylonian and Sumerian empires in Mesopotamia are examples of past civilizations whose collapse, in part, was caused by poorly practiced irrigation and drainage.

Fig. 1 Population, irrigated areas and major broad acre crops (maize, wheat, rice and soybean) production (1960–2018). Compiled from on-line databases of the U.N. Food and Agriculture Organization (FAO-FAOSTAT, <http://www.fao.org/faostat/en/#data>).

Environmental effects of irrigated agriculture

Irrigation development has several positive socio-economic as well as ecological effects such as the creation of employment opportunities, rural development and poverty alleviation, transformation of drylands into green areas that produce large amounts of oxygen and fix carbon dioxide and accommodate, through fields, ditches, canals and reservoirs, the habitats where a wide range of wildlife thrives, as opposed to deserts and undeveloped natural arid lands (Angelakis et al., 2020). A comparative study shows that irrigation generally has a positive effect on soil fertility under arid conditions and a negative effect in semi-arid, semi-humid and humid tropical zones (Nikolskii et al., 2019).

Some of these effects can also be considered negative from the ecological point of view, since they alter or even destroy natural ecosystems in arid and semiarid regions. For example irrigation projects, that transform large areas of dry cereal agro-ecosystems into irrigated crop systems dominated by maize, erode plant diversity in Spain (Fagúndez et al., 2016). Irrigation causes far-reaching land transformation, which is often permanent and irreversible and takes place mainly in two ways: (a) through direct modifications of the land surface, which occur when water conveyance and distribution networks are constructed, and lands are cleared, shaped and leveled for farming and irrigation; and (b) through in-depth transformations that take place when the water and salt balance in the region are changed as a consequence of importing large quantities of water and salts into the area (see Squatriti, 2002 in Angelakis et al., 2020).

Dam construction and, more importantly, water withdrawals from groundwater and surface water have altered not only freshwater flow dynamics (see Döll et al., 2009 in Siebert et al., 2015) but also variations in water storage in surface water bodies and aquifers (see Döll et al., 2012 in Siebert et al., 2015). Overexploitation of groundwater, changing flow regimes of rivers, and rising water tables are some of the environmental issues to be addressed. Excessive water usage triggers drainage and salinity problems, which may cause irreversible loss of soil fertility. Erosion and sedimentation, as well as salinization, have gone 'hand-in-hand' with the deterioration of farmland and the eventual collapse of some social structures. At the same time, salts, organic matter, solids of several sizes, fertilizers and pesticides may leach from the soil and run off into rivers, streams or aquifers, together with microorganisms and several pathogens. Furthermore, large bodies of water stored in dams and diversion channels can cause significant changes in local climate, while the extent of wetlands that have important ecological functions of biodiversity, nutrient retention and flood control can be reduced.

Water shortage

Global water use has increased six fold over the past 100 years and continues to grow steadily at a rate of about 1% per year as a result of increasing population, economic development and shifting consumption patterns (UNESCO, 2020). The demand for fresh water increased fourfold during the period 1950–1960 only, compared to the previous decades, due to the implementation of new irrigation projects and the increase in demand for municipal and industrial water. Global water demand is projected to increase by 20 to 30% by 2050 (see UNESCO, 2018 in UNESCO, 2020). Approximately 3.2 billion people live in water-scarce agricultural areas, of whom, 1.2 billion live in severely water-constrained agricultural areas. Population growth is a key driver of water scarcity as it implies rising demand for this precious natural resource. Consequently, the annual amount of available freshwater resources per person has declined by more than 20% in the past two decades. More than 60% of irrigated cropland (171 Mha) is highly water-stressed (FAO, 2020).

Globally, irrigated agriculture uses the highest portion (72%) of the world's water resources (Fig. 2) (UN-Water, 2021), and accounts for over 90% in arid countries (FAO, 2018). Groundwater irrigation plays a vital role in boosting agricultural production and livelihoods of rural communities in many parts of the world. For example, the area in South Asia equipped for irrigation has tripled since 1950 (Siebert et al., 2015). India, Pakistan, and Bangladesh are the largest groundwater users in South Asia, and more

Fig. 2 Percentage of water withdrawal by sector and continent. FAO-AQUASTAT database (http://www.fao.org/nr/water/aquastat/water_use/index.stm).

Fig. 3 Water distribution by open concrete canals throughout the fields (A), water withdrawal from those canals to the field-head ditches (B) and water application by flooding irrigation method (C).

than 85% is used for agricultural purposes, compared to 40% in the rest of the World (Siebert et al., 2015; Chindarkar and Grafton, 2019). These three countries irrigate 48 Mha using groundwater, approximately 42% of the global groundwater-fed cropland (see Mukherjee et al., 2014 in Qureshi, 2020). An estimated 35.9 Mha of agricultural lands are subject to the indirect use of urban wastewater (Thebo et al., 2017).

Water consumption by crops is only a small portion of the total water diverted to irrigated agriculture because of losses in conveyance networks, poor water application efficiency, excess water application due to inappropriate water management, policies and unrealistically low water pricing. The delivery efficiency of the Indus irrigation system (consisting of perennial rivers, a network of unlined canals, and distribution channels) is only 36%. Similar surveys from Europe indicate that in open canal distribution networks, water losses are estimated at up to 40% in unlined ditches and up to 25% in lined canals. The efficiency of irrigation application ranged from 45% to a maximum of 60% in areas where water was distributed via open canals. Greater irrigation efficiencies have been achieved in pipe systems (e.g. Phocaides, 2007). The water use efficiency (WUE) in irrigated agriculture increased up to 44% globally, varying between the regions and countries: low in Southeast Asia (19%) and sub-Saharan Africa (30%) and high in Northern Africa (69%) and South Asia (55%) in the early 2000s compared to late 1990s (FAO, 2011). Despite technical advances, WUE in Pakistan ranges between 35% and 40% (see Khan et al., 2008 in Qureshi, 2020) which is a result of the application of excess irrigation water by the flood irrigation method (Qureshi, 2020). The Fig. 3 shows examples of water distribution by open concrete canals throughout the fields, water withdrawal from those canals to the field-head ditches and water application by the flood irrigation method.

The global average 'economic water productivity', which is defined as the value added per volume of water withdrawn in all water-using sectors, has increased 4% globally since 2015 and is around USD 15 m⁻³. Significant differences exist among countries and regions, the lowest regional economic water productivities are USD 2 m⁻³ in Central and Southern Asia, around USD 7 m⁻³ in sub-Saharan Africa where the irrigated areas have more than doubled since 1960. The highest values are USD 50 m⁻³ in Oceania and USD 38 m⁻³ in Europe and North America (UN-Water, 2021; FAO, 2018).

The source of the water withdrawn (groundwater or surface water) affects water storage in surface water bodies and aquifers in different ways. For example, in regions with extensive surface water withdrawals for irrigation, such as Southern China, net abstractions from groundwater are negative, i.e. groundwater is recharged by irrigation. The opposite occurs in areas dominated by groundwater withdrawals for irrigation, such as in the High Plains aquifer of the central USA, where net abstraction of surface water is negative because return flow of withdrawn groundwater recharges the surface water compartments (see Döll et al., 2012 in Siebert et al., 2015).

With overexploitation of groundwater resources for irrigation in many countries, aquifer depletion has been observed for many semi-arid and arid regions. More than one million deep wells are opened annually in the Indian peninsula and Pakistan. In the Baluchistan province of Pakistan, groundwater tables are declining at a rate of 2 to 3 m annually, and without effective management measures about 20% of the agricultural areas may lose access to groundwater by 2025 (see Tariq et al., 2020 in Qureshi, 2020). The

water table depth in Northern China increased from 8 to 50 m between 1967 and 2000. Similarly, it was reported that water levels of 10 aquifers in Mexico decreased by 1.8–3.3 m annually. In the USA and Mexico, around 20% of irrigation water comes from non-renewable groundwater. In Iran and Saudi Arabia, where rainfall and surface freshwater are extremely scarce, non-renewable groundwater provides the largest contribution to irrigation water, 40 and 77% respectively (Wada, 2012). In India, cropping intensity is expected to decrease by 20% nationwide and by 68% in groundwater depleted regions in 2025 (Jain et al., 2021).

Overexploitation of aquifers and the use of groundwater from deeper aquifers for irrigation can cause secondary salination in agricultural lands (see Greene et al., 2016 in Mastrocicco and Colombani, 2021) since groundwater salinity and some natural (geogenic) hazardous elements tend to increase with increasing depth (van Weert et al., 2009). The contamination due to geogenic sources such as arsenic, fluoride, and iron as well as salinity problems in coastal and inland areas are the major land and water quality issues in many parts of the world e.g. in India (Garduño et al., 2011), the Indus Basin in Pakistan and the Murray-Darling Basin in Australia (see Greene et al., 2016 in Mastrocicco and Colombani, 2021) and Mediterranean countries (Mastrocicco and Colombani, 2021).

Furthermore, overexploitation of deep wells close to coastal areas triggers seawater intrusion and thereby causes degradation of water quality, which in turn endangers the sustainability of irrigated agriculture. As a result of groundwater overexploitation, land subsidence triggered by aquifer compaction can be observed, resulting in high socio-economic impacts for the affected communities such as in the Konya closed Basin in the Central Anatolian region of Turkey (Caló et al., 2017). Mexico City has experienced land subsidence up to 30 cm year⁻¹ due to massive GW extraction for municipal and agricultural water use, resulting in decreasing water resources, damaging infrastructure, and increasing flood risk and water contamination (see Chaussard et al., 2014 in Caló et al., 2017).

Irrigation withdrawals have also contributed to the shrinkage of vast lakes: Lake Chapala in Mexico lost 80% of its volume between 1979 and 2001, and the Aral Sea almost disappeared by the end of the 20th century as irrigation withdrawals for cotton (*Gossypium hirsutum* L.) reduced inflow (FAO, 2011). Climate change may also exacerbate the situation in water-scarce regions in the world. Thus, on the one hand climate change could increase water demand for agriculture, primarily for irrigation, due to prolonged dry periods and severe drought (FAO, 2020), but on the other hand the share of water available for agriculture is expected to decline to 40% by 2050 (OECD, 2012).

Waterlogging and salinity

Salinity problems associated with irrigated agriculture have been recognized for a long time. Salinity causes several problems such as poor soil structures particularly due to sodium, poor plant growth and less yield, ecological and socio-economic problems and also food insecurity. Soil salinity that develops because of mismanaged farm irrigation systems is called secondary salinity. Excess use of irrigation water (Fig. 3) can cause a rise in the water table, and the resulting problem from waterlogging can become a major constraint to high crop yields. Soil salinity and waterlogging are interrelated and both occur due to lack of drainage and excess irrigation-water application. These problems, however, are often ignored at the planning stage of irrigation projects. This is not because of the lack of technical understanding, but mainly because of populist political considerations and commitments to extend irrigated acreage to larger areas without drainage. Drainage systems are largely underground, and therefore have the least political appeal. The value of the drainage systems is difficult to appreciate in the short term, since they function as preventive measures for soil salinization that may occur in the future.

In areas lacking properly designed drainage systems, the water table soon rises to the soil surface, continuing evaporation takes place, and salt accumulation speeds up (Fig. 4). Waterlogged soils can also collapse quickly through dispersion of clay particles, which is especially the case in dispersive or sodic soils. Furthermore, roads and building foundations can be weakened by an accumulation of salts within the natural soil structure. Waterlogging within the rootzone leads to depletion of soil oxygen and carbon dioxide accumulation, chemical conversion of non-toxic chemicals into their reduced form (which can be toxic, e.g., sulfate reduced to sulfide), denitrification and emission of nitrous oxide (N₂O), one of the major greenhouse gases, and reduction in nitrogen fixation by the nodules of legume crops (see IPBES, 2018 in UNESCO, 2020).

The global area of all salt-affected soils, most of which are naturally salty, is about 1000 Mha; they occur in about 100 countries (see IPBES, 2018 in UNESCO, 2020). Irrigated land damaged by salinization is estimated globally to be 60 Mha and the top eight contributing countries are Pakistan (3.2 Mha), China (7 Mha), USA (5.2 Mha), India (20 Mha) (Squires and Glenn, 2011), Uzbekistan, Iran, Iraq and Turkey. An additional 60–80 Mha are affected to some extent by waterlogging and related salinity (FAO, 2011). Some well-known regions where salinization occurs include the Aral Sea Basin in Central Asia, the Indo-Gangetic Basin in India, the Indus Basin in Pakistan, the Yellow River Basin in China, the Euphrates Basin in Syria and Iraq, the Murray-Darling Basin in Australia, and the San Joaquin Valley in USA (Qadir et al., 2014). In the Indus Basin 21% of the total irrigated area, which produces more than 90% of Pakistan's grain, is currently affected by salinity. In the populous Sindh province, 43% of the irrigated area is affected (Qureshi, 2020). About 10% of all river stretches in Africa and Asia have high salinity levels primarily associated with agricultural irrigation (see UNEP, 2016 in UNESCO, 2020).

The cost of salt-induced land degradation in 2013 was USD 441 per hectare; a simple benefit transfer suggests the annual economic losses could be 27 billion USD (Qadir et al., 2014). It is estimated that the areal extent of naturally occurring and human-induced salt-affected soils are increasing due to enlargement of irrigated areas and the impact of climate change.

Fig. 4 Soil salinity in Harran Plain in Turkey. Photo by M. Ali Çullu.

Pollutants attributable to irrigation

Excessive and inefficient irrigation can affect soil and water quality by causing erosion, transporting nutrients, pesticides, and 'heavy metals.'

Sediment load carried in returning waters from large-scale irrigation projects and erosion occurring in watersheds may be a source of major pollutants and result in serious environmental consequences. There are two different sources of soil erosion: (1) erosion occurring during a flood that silts up water reservoirs, (2) erosion in areas with poorly planned irrigation projects where land capability classifications are disregarded, and surface irrigation methods are practiced with no grading of the land. Sediments originating from the erosion of fertile surface soil in agricultural areas are carried to downstream areas in returning irrigation waters.

Water reservoirs, man-made small lakes, and large dams may be filled with silt from erosion before they complete their economic life, if forestation is not planned and implemented. Silt and sediments found in water reservoirs may also carry plant nutrients (that may cause algal blooms) and pesticide residues (with the risk of serious health effects). Heavy metals are also transported into water reservoirs by soil erosion.

Plant nutrients (fertilizers)

Use of fertilizers is a successful low-cost means of achieving high crop yields under irrigation. As a result fertilizer demand has increased globally, supported by global economic growth, leading to an excessive application of fertilizers: "the more, the better". According to the FAO statistics, world NPK (nitrogen, phosphorus, potassium) fertilizer consumption reached 188 million tons (MT) in 2018 (Fig. 5) and is expected to increase to 231 and 263 MT by 2030 and 2050, respectively (Alexandratos and Bruinsma, 2012) unless sustainable strategies such as improved water and fertilizer management, use of cover crops and fertilizer technology are widely practiced to increase nutrient-use efficiency and reduce nitrate leaching.

Only 30–50% of applied nitrogen fertilizer (e.g. Cassman et al., 2002) and ~45% of phosphorus fertilizer (Smil, 2000) is taken up by crops, and significant amounts of the applied nitrogen and phosphorus remain in the soil after the crops have been harvested. Excessive application of fertilizers and manure or inefficient use of the main nutrients (N and P) in fertilizers are the main contributors to environmental issues linked to agriculture; these failures also increase the production costs for the farmers. Such non-point nutrient losses pollute soil resources, harm off-site ecosystems, degrade water quality and aquatic ecosystems, and contribute to greenhouse gas emissions.

In irrigated agriculture, excessive water application increases nitrate leaching, leading to a vicious circle where low nitrogen (N) availability is compensated for by increasing fertilizer applications which result in low nitrogen use efficiency (NUE) by the

Fig. 5 Annual fertilizer consumption by continent (1961–2018). (Compiled from FAOSTAT–Agricultural Data, FAO on-line database.)

crops and a deleterious impact on groundwater. Total global leaching and run-off of nitrogen is estimated at 32.6 million tons per year, the large majority from poor agricultural practices (Mekonnen and Hoekstra, 2015).

Nitrate fertilizers have high solubility, and the nitrate ion is easily leached into groundwaters with the application of excess irrigation water because of its strong mobility. Return flows from irrigated areas with high sediment loads may also contain large nitrate concentrations. The increase in nitrate and phosphorus in lakes is the main cause of eutrophication, algal blooms, and depletion of oxygen, which in turn can lead to the mass die-off of fish and it can also reduce fattening in cattle. Various parts of the worldwide have nitrate values higher than the WHO standards (50 ppm), and nitrate pollution from both rainfed and irrigated agriculture and, specifically, from the use of fertilizers and pesticides, is a common denominator on all continents (Abascal et al., 2022).

Water and nitrogen availability remain, globally, the most limiting factors for crop growth (Mueller et al., 2012). Therefore, irrigated agriculture requires specific farm water management practices to increase water- and nitrogen-use efficiency that may differ from rainfed systems. Results of a meta-analysis showed that improved water management, for example adjusting irrigation application to crop water requirements, using deficit irrigation techniques, improved irrigation scheduling, and water saving irrigation technologies such as drip irrigation, can help to optimize this. These approaches provide the most effective strategy and treatments for reducing nitrate leaching, followed by practicing improved fertilizer management, use of cover crops and use of improved fertilizer technologies (Quemada et al., 2013). The application of fertilizers and chemicals such as pesticides to crops together with water through the drip or sprinkler system is known as fertigation or chemigation. Fertilizers and plant protection chemicals that are water soluble can be applied efficiently and directly to the plants and or plant rootzone at the required time and in the right amount through the drip irrigation system. Compared to conventional methods of fertilizer application under flood irrigation, fertigation and chemigation prevent pollution by increasing the efficiency of fertilizer and pesticide use, in addition to increasing the efficiency of irrigation application under drip irrigation (Fig. 6).

Pesticides

Evaporation from large bodies of water stored in dams, networks of channels, and large irrigated fields contributes to increasing humidity, which in turn creates a favorable environment for the spread of plant diseases and pests. This has led to the use of pesticides, one of the major inputs of irrigated agriculture, which dates back to as early as the fifteenth century when arsenic salts were used as herbicides and insecticides. Growers prefer to grow crops of high cash value under irrigated agriculture resulting in the widespread practice of continuous monoculture, which can lead to pest and disease problems.

Only 1% of total pesticides are used effectively to control insect pests on target plants (see Bernardes et al., 2015 in Tudi et al., 2021), the remaining pesticides penetrate or reach non-target plants and environmental media. Irrigation practices play a major role in the transport and then accumulation of pesticide residues encountered in water resources. Irrigating at a rate that exceeds the rate of infiltration of soil promotes runoff that can carry pesticides with it. Irrigation that promotes deep percolation of water beyond the root zone of plants also causes the leaching of agro-chemicals such as pesticides to ground water. Both types of water movement, runoff and deep percolation, are of particular concern in areas where surface irrigation methods such as flooding are practiced. In addition, the frequent irrigation of coarse-textured soils and use of surface irrigation methods on sloping lands can also increase the risk of pesticide transport and accumulation in surface and ground water resources (SDWF, 2022).

Climate change affects pest and disease outbreaks and also accelerates the pesticide behavior of volatilization, runoff, leaching processes, and pesticide degradation (Tudi et al., 2021). There are many reports about pesticide contamination of both surface water and groundwater worldwide (e.g. see Brauns et al., 2018 and Aravinna et al., 2018 in Tudi et al., 2021). For example, the United States Geological Survey (USGS) found several pesticides in more than 90% of water and fish samples collected from streams in the USA (see Rose et al., 2018 in Tudi et al., 2021).

Fig. 6 An example of a simple drip irrigation system: (A) control unit including filter and fertilizer tanks, control valves, (B) main and lateral water distribution pipes and drippers near the plant rows.

A study of over 2000 agricultural workers in Africa, Asia, and Latin America found that many workers suffered from acute pesticide poisoning and reported the following symptoms: chronic headaches, dizziness, convulsions, and nausea (PAN, 2010). About 3000 children were poisoned by pesticides in eastern China's Zhejiang province, where irrigated agriculture is dominant, between 2006 and 2015, with most cases occurring during the farming season (Fan, 2017).

Metals

Fertilizers and pesticides that are used in irrigated agriculture contain a wide array of metals such as arsenic (As), boron (B), mercury (Hg), copper (Cu), cadmium (Cd), lead (Pb), nickel (Ni), and zinc (Zn). While boron is often added to the soil with irrigation water, arsenic (see Varol and Şekerçi, 2018 in Abascal et al., 2022) is included in many insecticides and herbicides, and phosphorus fertilizers are the major source of zinc and cadmium pollution (see in Mazhar and Ahmad, 2020 in Abascal et al., 2022) in soils and groundwater. In addition, the presence of nitrates from the use of chemical fertilizers implies the co-existence of other ions in groundwater, such as F^- (fluoride), SO_4^{2-} (sulfate), and K^+ (see Roy et al., 2020 in Abascal et al., 2022). Runoff and tail waters carrying sediments from irrigated areas often contain metals that are discharged into drainage channels and then mixed with other surface water resources. These may cause serious environmental damage such as the selenium (Se) pollution reported in the San Francisco Delta area in the American West (Presser and Luoma, 2006). Prevailing intensive irrigation has caused selenium enrichment in groundwater and also its accumulation in soils in Punjab. Similarly, irrigation has been found to be a critical source of Hg (38.63%) and Ni (22.69%) in Zhejiang province in China (Ma et al., 2021).

Public health concerns

In large-scale irrigation schemes, the large bodies of water stored by dams and water-conveying open-channel systems and related local climate change may cause an increase in pests and parasites that carry diseases. Among the diseases spread by parasites and insects feeding in water sources are malaria, dengue fever and the Zika virus, schistosomiasis (bilharzia), yellow fever, encephalitis, and river blindness. Encephalitis is largely found in the rice fields of South, Southeast, and West Asia; lymphatic filariasis, across all continents; river blindness, largely in Africa and Central America; and malaria and schistosomiasis, across all continents but largely in Africa. A study on the incidence of malaria found that the large dams in major river basins of sub-Saharan Africa increased cases from 0.9 to 1.7 million annually depending on the year and the malarial burden (Kibret et al., 2021). Of the approximately 800 million people at risk of schistosomiasis worldwide, 100 million live in close proximity to dams and irrigation schemes (see Steinmann et al., 2006 in Lund et al., 2021).

Large nitrate concentrations in drinking water as a result of fertilizer use in irrigated agriculture is also a public health threat, causing the deadly health disorder methemoglobinemia, particularly in human infants.

In water-scarce regions, municipal and industrial wastewaters are often recycled and rerouted into irrigation schemes. Although treatment of such water sources is common practice in the developed world, it is rare in developing countries. Wastewater from

poultry farms, cattle ranges, and household sewage may pose a serious health hazard if used for the irrigation of freshly consumed vegetables. Among the diseases spread by the use of untreated wastewater for irrigation are cholera, typhoid, ascariasis, amebiasis, giardiasis, and entero-invasive *Escherichia coli* (e.g. [Blumenthal and Peasey, 2002](#)). In addition to regulatory mechanisms and controls of water quality used for irrigating crops that are eaten without cooking (e.g. leafy salad crops), it is suggested that controlling the water source, regime, and timing of irrigation may help to reduce harmful contamination ([Banach and van der Fels-Klerx, 2020](#)).

Use of untreated wastewater for irrigation causes the transfer of Pb, Cd, and Ni from the roots to the edible parts of vegetables, posing a long-term health risk for example in India (Sharma et al., 2007 in [Ahmed et al., 2018](#)) and in Bangladesh (see Tasrina et al., 2015 in [Ahmed et al., 2018](#)). Metals related to wastewater irrigation, and intensive fertilizer and pesticide applications, both in irrigated and rainfed agriculture, affect human health. The health problems depend on the ingested dose of such metals; they range from excessive shyness to simple stomach ailments, nausea, vomiting and diarrhea, to blood, lung, kidney complications or diseases, gastrointestinal cancer and even death. In particular young children and unborn fetuses are highly sensitive (e.g. [Andrews and Henrique, 2006](#)).

Sustainability

Sustainable irrigation development has to be capable of delivering a constant and reliable supply of water of sufficient quality for irrigation to support a constant or increasing level of food production, while keeping its impact on the environment within sustainable levels. Implementation of integrated approaches for land and water resources management comprising integrated plant nutrient and pest management and crop–livestock systems can promote the sustainability of irrigated agriculture.

The history of agriculture has shown that sustainable irrigated agriculture requires adequate salt balance and drainage, in addition to water balance for sustainable soil and water resources management. The technology to accomplish this exists, but its use is limited by: lack of economic incentives for growers to improve their existing irrigation structures; need for investment in pressurized irrigation systems and drainage works; lack of training in and experience with effective management practices; public opposition to the possible effects of irrigation return flows on the environment; and administrative constraints such as low budget allocations for timely maintenance and management of irrigation schemes.

Conclusions and outlook

Irrigation enables agricultural production in arid regions where precipitation is insufficient to meet plant water requirements. In humid and sub-humid regions, applied irrigation water supplements available soil moisture and facilitates high crop yields and quality by providing a critical buffer against periodic droughts. Crop yields under irrigation can be increased by up to 500% compared to rainfed agriculture. This makes irrigation a vital part of the agricultural economy in many countries.

However, increasing competition between water using sectors, overextraction of groundwater reserves, decreases in quantity and quality of surface water resources, shifts in climatic conditions are constraining the ability of hydrological systems to meet irrigation needs in many agricultural regions of the world. In particular, projected increases in the frequency and severity of droughts will probably increase future agricultural water demand in arid and semiarid regions. In addition, excess use of water in many irrigated lands causes deterioration of the soil and water resources, which not only harms the environment but also diminishes the productivity of irrigated agriculture. Hence, the resilience of irrigated agriculture will depend on the successful implementation of sustainable irrigation policies and management strategies to adapt to water scarcity and to reduce related environmental effects.

Effective strategies and practices for integrated land and water resources management may increase resource productivity while reducing the negative effects. Inefficient use of pesticides can be replaced with integrated pest management practices. On-farm water conservation strategies, such as improved land leveling, zero tillage, cover crops and advanced irrigation technologies, such as drip irrigation, have the potential to save a significant amount of water, reduce nutrient losses and save energy. Smart and precision agriculture strategies, which enable the applications of inputs (seed, water, fertilizer, pesticides, etc.) to be only as much as, when and where needed, can help to increase resource use efficiency and protect the environment. However, the negative environmental effects of irrigation can only be significantly minimized once sustainable living strategies such as reducing food loss and waste are practiced together with sustainable irrigated agriculture.

Abstract

Most governments in developing countries do not invest enough to treat wastewater, therefore, the farmers use untreated wastewater for irrigation. The positive aspects of such irrigation are a reliable and year-round water source, little or no spending on fertilizer, less pumping cost than with groundwater, an increase in soil organic matter, and greater income from market-ready crops. The negative risks include imbalanced nutrient addition, salinity, metal ion contamination, emerging contaminants, and potential exposure of farmers and consumers to pathogens and contaminants. Balancing these tradeoffs requires ensuring positive outcomes while minimizing risks through wastewater treatment and use compatible with its quality.

Key points

- Wastewater irrigation has increased over time because of rising volumes of wastewater from population growth, urbanization, and higher living standards coupled with growing urban demand for food, forage, and other urban and peri-urban agricultural produce.
- There is a large variation between developed and developing countries as well as among countries within different economic groups regarding safe management of wastewater.
- Positive aspects of wastewater irrigation are a year-round water supply, savings on fertilizer, less pumping cost, increase in soil organic matter, and greater income from high-value crops.
- Negative risks include imbalanced plant nutrient application, increased soil salinity, metal ion pollution, and exposure to emerging contaminants and pathogens.
- Safe and productive use of wastewater in agriculture helps in improving livelihoods of farming communities whilst protecting the environment and human and animal health.

Introduction

Freshwater ecosystems provide a range of crucial services such as drinking water, water for agriculture and energy, natural solutions for water purification and climate resilience, and habitats for fish and other aquatic species as well as recreation and tourism. Whilst the overall balance of freshwater at the global level suggests enough freshwater availability, freshwater scarcity has increased over time in specific regions, countries, and parts of countries due to uneven distribution of human population densities and water resources. Climate change and shifting weather and rainfall patterns have triggered freshwater scarcity (World Bank, 2018), which is expected to persist and deepen in arid and semi-arid areas, including those with dense population.

Recognized as a key challenge to sustainable development, freshwater scarcity is considered as a prospective cause of tensions within and across countries (UN-Water, 2020). Water-scarce areas characteristically fall under arid and semi-arid climates and depend on some combination of seasonal rainfall, mountain headwater runoff, and groundwater (with aquifers being non-renewable in most situations). Such areas have very few rivers, often originating in other countries. In addressing the water scarcity challenge, water-scarce countries and communities need to consider alternatives to conventional water resources to narrow

Fig. 1 Wastewater treatment (%) at the country scale. the water demand–supply gap. In this regard, safe collection and treatment of municipal wastewater and its productive use offer a significant opportunity (Jones et al., 2021; Faruqui et al., 2004).

Although agriculture is the dominant user of freshwater in water-scarce areas, the sector has been conceding its share gradually to household, municipal, and industrial activities where demand is increasing rapidly. Since the use of freshwater in domestic, municipal, and industrial sectors generates wastewater, the volumes of wastewater are on the increase and available for fit-for-purpose use in agriculture after pertinent treatment (Qadir et al., 2020). Fit-for-purpose use is defined as treating wastewater to a water quality standard acceptable by a specific user. Thus, fit-for-purpose treatment can optimize the water quality for its next role. For example, most non-potable use options for wastewater require a quality lower than that of drinking water, so that secondary treatment is often adequate for irrigation of non-food crops (WWAP, 2017).

Given water scarcity, the use of treated wastewater needs to be a common practice in water-scarce areas. In contrast, the use of large volumes of untreated or inadequately treated wastewater in agriculture is common in developing countries (Jones et al., 2021). Despite multiple demonstrated benefits of safely managed wastewater for the farmers and associated communities, the progress regarding wastewater treatment and fit-for-purpose use of treated wastewater remains very slow in most developing countries. Countries with different levels of economic development demonstrate large variation in wastewater treatment (Fig. 1). On average, the countries falling under the high-income category treat 70–74% of the wastewater generated, followed by upper-middle-income countries (38–43%), lower-middle-income countries (26–28%), and finally low-income countries (4–8%) (Sato et al., 2013; Jones et al., 2021). The drivers behind wastewater reuse are a complex mixture of social, economic, geographic, and hydrological factors, and data are very limited globally. An estimated 41 billion km³ of treated wastewater is intentionally used (Jones et al., 2021), particularly in the Middle East and North Africa, Australia, western North America, and southern Europe.

By acknowledging the importance of water quality protection and wastewater treatment, the 2030 Agenda for Sustainable Development has a specific target in the Sustainable Development Goal (SDG) 6, which addresses safe water and sanitation for all. Addressing water quality and wastewater treatment explicitly, SDG Target 6.3 states: “By 2030, improve water quality by reducing pollution, eliminating dumping and minimizing release of hazardous chemicals and materials, halving the proportion of untreated wastewater and substantially increasing recycling and safe reuse globally.”

This chapter provides an overview of wastewater irrigation and assesses the tradeoffs between the positive aspects of wastewater irrigation (year-round water supply, savings on fertilizer, less pumping cost, increase in soil organic matter, and greater income from high-value crops) in relation to the negative risks (imbalanced soil nutrient application, increased soil salinity, metal ion pollution, and exposure to emerging contaminants and pathogens).

Wastewater use for irrigation

While wastewater has multiple uses—agricultural and landscape irrigation, groundwater recharge, agroforestry systems, aquaculture, cooling of thermoelectric power stations, dust control, and instream ecological conservation—its most prevalent use remains for agricultural and landscape irrigation (WWAP, 2017). In most developing countries, large volumes of untreated wastewater

Fig. 2 Municipal wastewater is a valuable source of water, nutrients, and energy, but large volumes are released to the environment in untreated form. Farmers in dry areas pump untreated wastewater to irrigate nearby fields. Credit: Manzoor Qadir.

are used for irrigation in urban and peri-urban settings (Fig. 2) where farmers' land holdings are small and these farmers are not able to optimize the volume or quality of the wastewater they receive (Qadir et al., 2010; Jones et al., 2021).

A two decades-old estimate of wastewater irrigation suggested an area of up to 20 million ha worldwide (Scott et al., 2004 citing 2001 work); this estimate was also cited in Jiménez and Asano (2008). Later, a global, spatially explicit assessment of wastewater-irrigated areas reveals the area under direct and indirect wastewater irrigation at 36 million ha, of which 29 million ha are likely to be exposed to untreated wastewater flows (Thebo et al., 2017). These estimates consider a cropping intensity of 1.48 and wastewater irrigation in both diluted and undiluted forms. Using the same cropping intensity (1.48) considered by Thebo et al. (2017), recent estimates of wastewater production by Qadir et al. (2020) suggest an irrigation potential with undiluted wastewater at 42 million ha.

Despite increasing water scarcity and emerging problems of the deterioration in water quality coupled with climate change events, the developing countries in arid and semi-arid areas are far from achieving the desired levels of wastewater treatment. Wastewater treatment plants either do not exist or existing plants are overwhelmed by poor operation and maintenance. In the case of operational wastewater treatment plants, they are often run well beyond their design capacity as they receive more wastewater than the volumes for which they were designed to treat in a specific timeframe and a given efficiency (Sato et al., 2013). Such realities of wastewater treatment status on the ground question the technical feasibility and robustness of wastewater treatment processes (if they exist at all), and as a result, the quality of treated wastewater is highly variable, from no treatment to full treatment (Grangier et al., 2012). Although the policies and regulations prohibiting the agricultural use of untreated or inadequately treated wastewater are in place, they remain far from their desired implementation (Qadir et al., 2010).

Despite the benefits demonstrated, the use of wastewater for irrigation falls short of its potential due to a range of constraints, such as: (1) inadequate public budget allocation for adequate wastewater management—collection of domestic and industrial wastewater separately, their pertinent treatment, and safe use or disposal; (2) limited comprehensive assessments on the impacts of long-term irrigation with untreated wastewater on the environment and human health; (3) incomplete economic analyzes without undertaking sound assessments and feasibility studies on the anticipated benefits from resource recovery—water, nutrients, precious metals, and energy—and comparative evaluation of the costs of other alternate sources of water; (4) lack of cost-recovery mechanisms for safely managed wastewater to fund pertinent wastewater managed systems; (5) disparity between water pricing and regional or local water scarcity without valuing treated wastewater, leading to the shutting down of wastewater treatment plants or supplementing costs with substantial subsidies to keep the wastewater management systems functional; (6) lack of clarity on ownership or use rights over wastewater once it is treated and released from treatment plants to local water bodies; (7) lack of political will and effective public policies to prioritize and encourage implementation of water recycling and reuse systems; (8) lack of clarity among wastewater-related national agencies and local institutions for effective management of wastewater; (9) little understanding of soil properties such as their filter and buffering capacity while considering wastewater irrigation systems; and (10) lack of training and capacity development to produce skilled human resources capable of handling the complexity resulting from wastewater collection, treatment, and reuse systems.

In general, the lack of commitment on the part of several developing-country governments to advocate and support comprehensive wastewater treatment programs has led to the lack of understanding among farmers and households about the anticipated environmental and health benefits from wastewater treatment and irrigation with treated water (Sato et al., 2013). This contrasts with formal promotion of desalination as another water-scarcity adaptation mechanism, despite inherent tradeoffs in its use (Qadir et al., 2007; Wilder et al., 2016). Because the wastewater treatment plants in low- and lower-middle-income countries, if any, are away from urban areas, urban households do not greatly appreciate the benefits of wastewater treatment and reuse in water-scarce

environments. Although the governments in such situations collect fees for water connections and wastewater services, they do not invest enough on the treatment of wastewater. On the ground, the water resources management systems are inefficient in most developing countries and do not consider appropriately the potential gains from treated water as a precious resource, which can be used for a range of opportunities such as agricultural and landscape irrigation.

Tradeoffs of wastewater irrigation

Despite issues with the quality of untreated and inadequately treated wastewater and its reuse in agriculture, there are certain positive trade-offs of wastewater irrigation. Most farmers in water-scarce low-income and lower-middle-income countries and communities with access to wastewater do not hesitate to use it even in untreated or inadequately treated forms for irrigation (Qadir et al., 2010; WWAP, 2017). The reasons are that (1) wastewater is the only water source available for irrigation throughout the year, (2) its use for irrigation reduces the need for purchasing certain farm inputs like fertilizer as wastewater is rich in essential nutrients, (3) irrigation with wastewater involves less energy cost if the alternative clean water source is deep groundwater, (4) wastewater irrigation provides greater farm work opportunities due to high cropping intensities and yields, and (5) wastewater enables farmers in peri-urban areas to produce high-value crops for sale in nearby urban markets (Minhas and Samra, 2004; Murtaza et al., 2010).

A reliable supply of irrigation water and nutrients for crop growth are crucial inputs to agricultural production systems, therefore, wastewater irrigation delivers both inputs to a significant extent (Hamilton et al., 2005). This is crucial in situations where wastewater is the only source of irrigation water available throughout the year or where other sources of irrigation water are extremely limited to support viable irrigation systems (WWAP, 2017). As the farmers in wastewater-irrigated areas often have small land holdings, wastewater irrigation provides them with the opportunity to operate year-round farming systems, which help these farmers to increase their income per unit of land area while alleviating poverty (Fig. 3).

Together with positive benefits and controlling factors, there is a range of tradeoffs, which may be negative or positive depending on the treatment of wastewater or lack of it as well as the quality and availability of wastewater (Lazarova and Bahri, 2005; Vulliet et al., 2011; Montes-Grajales et al., 2017).

Nutrients

Although municipal wastewater is rich in nutrients, the concentrations of these nutrients vary widely as demonstrated in wastewater samples collected from different locations and sources (Qadir et al., 2020). Such nutrient concentrations also depend on wastewater treatment and nutrient removal processes during specific treatment processes. Based on data on wastewater quality from different locations in South Asia, the estimates reveal that concentrations of the nutrient elements are highly variable, for example nitrogen is found in the range of 11 and 98 mg L⁻¹ and phosphorous of 1–30 mg L⁻¹ (Qadir and Scott, 2010). Based on 53 wastewater quality datasets from across the world, Qadir et al. (2020) estimate the average concentrations of nitrogen as 43.7 mg L⁻¹ and phosphorus as 7.8 mg L⁻¹.

For the wastewater-irrigating farmers, the nutrients in wastewater are termed as a major driving force for irrigation with untreated wastewater (Table 1). As most farmers believe wastewater treatment removes most nutrients, they prefer untreated wastewater over

Fig. 3 Wastewater is an important asset for resource-poor farmers, supporting local livelihoods. Year-round supply often means fodder for animal feed is cultivated using wastewater. Credit: Jeroen Ensink.

Table 1 Potential contribution of irrigation with wastewater in terms of nutrient addition to the soil. Derived from the data on nutrient concentrations in 53 wastewater samples.

Nutrient	Nutrient concentration (mg L ⁻¹)	Fertilizer contribution (kg ha ⁻¹)		
		Irrigation rate (5000 m ³ ha ⁻¹)	Irrigation rate (8000 m ³ ha ⁻¹)	Irrigation rate (10,000 m ³ ha ⁻¹)
Nitrogen	43.7	219	350	437
Phosphorus	7.8	39	62	78
Potassium	16.5	83	132	165

From Qadir M, Drechsel P, Cisneros BJ, Kim Y, Pramanik A, Mehta P and Olaniyan O (2020) Global and regional potential of wastewater as a water, nutrient, and energy source. *Natural Resources Forum* 44: 40–51.

treated wastewater for irrigation. In contrast to farmers' perception, the evaluation of nutrient concentrations in untreated and treated wastewater suggests that treated wastewater contains sufficient nutrient concentrations to meet crop nutrient requirements (Yadav et al., 2002). In addition to macronutrients, a range of micronutrients such as iron, zinc, manganese, and copper are also added to the soil through wastewater irrigation.

While most wastewater contains enough nutrients to meet crop requirements, managing required concentrations of nutrients in wastewater is a challenge due to possible negative impacts stemming from their excessive addition to wastewater-irrigated soils. In the case of macronutrients such as nitrogen and phosphorus, there are three likely pathways: (1) discharge of nutrient-rich untreated and inadequately treated wastewater to freshwater bodies may pose a significant challenge to the receiving waters over the long run, causing eutrophication of natural water bodies, undesirable growth of algae and weeds in wastewater channels and soils; (2) surplus and uncontrolled nitrogen application through wastewater irrigation may lead to excessive vegetation and green biomass resulting in a delay in crop maturity and a consequent decrease in economic yield; and (3) leaching of nitrogen may cause groundwater pollution, and methaemoglobinemia in infants drinking such nitrate-rich groundwater. Methaemoglobinemia reduces the ability of blood to carry vital oxygen around the body. Nitrates are highly soluble and can easily be moved to groundwater through the soil profiles in wastewater-irrigated areas.

The fertilizer value of wastewater has great importance because nutrients in wastewater contribute to crop requirements, therefore, periodic monitoring is essential to estimate the nutrient loads in wastewater and adjust fertilizer applications accordingly (Lazarova and Bahri, 2005). In addition to the negative effects from excessive addition of nitrogen to wastewater-irrigated soils, such applications of nitrogen also lead to increased emissions of nitrous oxides into the atmosphere.

Pertinent management of municipal wastewater and recovery of excess nutrients such as nitrogen and phosphorus by the wastewater treatment process offers environmental protection from minimizing eutrophication, health benefits with the elimination of methaemoglobinemia, and financial benefits from the recovery of nutrients (UN-Water, 2020). A recent assessment of nutrient recovery from wastewater suggests that nutrient concentrations in wastewater can account for 14.4% of global demand for nitrogen and 6.8% for phosphorus as fertilizers. In terms of potential economic gains, the recovery of nitrogen and phosphorus from wastewater may generate annual revenue of \$11.3 billion (Qadir et al., 2020).

Organic matter and organic carbon

The occurrence of organic matter in wastewater may have a range of positive impacts on wastewater-irrigated soils depending on the nature of the organic material added through wastewater irrigation. The addition of organic matter to the soil through wastewater improves soil structure, acts as a store of nutrients essential to meet crop nutritional needs, and enhances soil chemical properties, such as cation exchange capacity. The latter helps to adsorb undesirable metal ions on the soil cation exchange complex and to decrease their availability in soil solution for plant uptake.

Beyond the beneficial effects on some soil chemical properties, wastewater irrigation improves certain soil physical characteristics, such as aggregate stability, water holding capacity, and hydraulic conductivity (Minhas and Samra, 2004). Periodic monitoring of these properties revealed a 24% increase in soil hydraulic conductivity after 15 years of wastewater irrigation, which was increased further to 39% after 25 years of wastewater irrigation when compared with freshwater-irrigated soils (Fig. 4). There was also an improvement in other soil physical properties investigated in the study (aggregate stability and water holding capacity). Such properties contribute to enhancing water storage in the soil, thereby increasing water use efficiency and crop productivity per unit of water and land. In another study on irrigation with wastewater for 3 years, Biswas and Mojid (2018) observed consistent but small increases in soil porosity, hydraulic conductivity, and water holding capacity in a soil irrigated with wastewater when compared with a freshwater-irrigated soil.

Field studies have shown that organic carbon in wastewater-irrigated soils increases regardless of soil characteristics. Minhas and Samra (2004) reported that long-term wastewater irrigation resulted in higher organic carbon levels than those irrigated with freshwater pumped from groundwater. For example, there was an 80% increase in soil organic carbon from 1.42% in

Fig. 4 Effects of 15 and 25 years of wastewater irrigation on some selected soil physical properties—aggregate stability (%), water holding capacity (%), and hydraulic conductivity (cm h^{-1})—when compared with freshwater irrigation. Modified from Minhas PS and Samra JS (2004) *Wastewater Use in Peri-Urban Agriculture: Impacts and Opportunities*. Karnal, India: Central Soil Salinity Research Institute. 75p.

freshwater-irrigated soils to 2.56% in wastewater-irrigated soil over a period of 15 years. Extending wastewater irrigation to 25 years resulted in an increase in soil organic carbon to 4.63% in wastewater-irrigated soil, suggesting a 226% increase over the freshwater-irrigated soil (Minhas and Samra, 2004). Organic and inorganic fractions of soil carbon are not only important for the soil to perform its agricultural productivity and environmental conservation functions, but also provide a pool of soil carbon that plays an important role in the global carbon cycle (Lal, 2004).

In contrast to a range of positive effects of organic matter added to wastewater-irrigated soils, there may be negative impacts resulting from (1) plugging of micro irrigation systems such as drippers and sprinklers; (2) hypoxic conditions in water holding bodies (tanks and ponds) due to depletion of dissolved oxygen; and (3) possibility of increased mortality in fish and other aquatic species (Qadir and Scott, 2010).

Salts

Wastewater contains a greater diversity of soluble salts than freshwater because it receives salts from a range of sources. The amount and type of salts used in a sector (domestic, municipal, industrial) affect the quality of wastewater it generates. For example, in the tannery industry, animal skins are usually salted with 50–100% salt and hides with 40–50% salt on a mass basis (Money et al., 2009). Such a large input of salt in the tannery industry generates wastewater containing salt concentrations in the range of $10\text{--}50\text{ g L}^{-1}$ ($16\text{--}80\text{ dS m}^{-1}$). For comparison, salt concentrations in domestic wastewater are low and range from $0.3\text{ to }0.5\text{ g L}^{-1}$ ($0.5\text{--}0.8\text{ dS m}^{-1}$), although both tannery and domestic wastewaters are broadly categorized as wastewater (Lazarova and Bahri, 2005).

Wastewater quality gets more complex when industrial waste streams are not discharged into separate sewers, rather into main municipal wastewater channels that carry wastewater to the treatment plants or to the channels carrying wastewater to farmers' fields. The challenge with the mixed wastewater is the removal of salt as the technologies (cation exchange resins or reverse osmosis membranes) are costly to ensure good-quality water (Toze, 2006; Qadir, 2018).

The amount and type of salts in wastewater and the treatment of wastewater or lack of it affect the quality of wastewater it generates. The effects of excess concentrations of salts in wastewater (saline wastewater) are different from those dominated by excess levels of sodium (sodic wastewater) (Oster et al., 2016; Qadir et al., 2021). Long-term irrigation with sodium-rich wastewater may result in the development of sodic soils, which exhibit structural problems driven by certain physical processes. Such soil degradation processes and conditions alter the geometry of soil pores, thereby affecting soil hydraulic properties such as infiltration rate and hydraulic conductivity. Such soil structural degradation may affect root penetration, seedling emergence, surface runoff, erosion, and tillage operations. After field studies for 8 years while irrigating olives with wastewater, Erel et al. (2019) found a steady increase in soil sodicity (higher exchangeable sodium percentage) in the wastewater-irrigated site reaching nearly double that of the freshwater site. They recommended close monitoring of soil sodicity while irrigating with wastewater to avoid soil degradation and allow consideration of practices leading to soil remediation.

Some industries release wastewaters with elevated levels of magnesium and potassium together with sodium. This is especially the case for wastewaters generated by dairies, piggeries, wineries, and olive or tomato processing plants. Research and practice in

recent years have demonstrated adverse effects of potassium and magnesium, in addition to sodium, on soil structure with degradation occurring through reduction in water movement into and through irrigated soils (Rengasamy and Marchuk, 2011; Smith et al., 2015). With increasing concentrations of potassium and magnesium in wastewaters (Oster et al., 2016), there is a need for a reassessment of the guidelines on irrigation water quality by considering the scale of the potential negative impacts of these cations to ensure the long-term sustainability of irrigated agriculture (Qadir et al., 2021).

Irrigation with saline and sodic wastewater may also affect groundwater quality. Wastewater generated from some industries, such as effluent from tanneries, is a major cause of groundwater contamination in surrounding areas and consequently may become a major socio-political issue, in addition to its environmental implications (Money et al., 2009). In the case of well-drained soils, salts and other contaminants may move through the soil profile into unconfined aquifers. The quality of wastewater in terms of salt concentration, soil characteristics such as texture and drainage, and the initial quality of the receiving groundwater are important factors that determine the extent to which salts in wastewater can affect groundwater quality. If the groundwater has high inherent salt concentration, then additional salt entering the groundwater from the soil will have a limited effect. But where groundwater has lower salt concentration, the impact of some salt addition may not be too adverse if the groundwater is not used for any other nearby purposes, e.g., drinking water supply.

Metal and metalloids

A range of metal ions and metalloids are essential for adequate plant growth, but they become toxic at elevated concentrations beyond permissible limits. Certain potentially toxic metals and metalloids are naturally present in the environment in trace amounts and are ingested with food, water, and air. Several of these metals and metalloids are of particular concern due to their adverse effects on agricultural productivity as well as on environment health (Gupta et al., 2012). For example, metal ions such as cadmium, mercury, and lead do not have essential functions, but they are detrimental, even in small quantities, to plants, animals and humans, and accumulate because of their long biological half-life (Hamilton et al., 2005). Other metals and metalloids, such as manganese, zinc, and copper are essential micro-nutrients in small concentrations, but harmful to crops when they surpass maximum allowable concentrations (Table 2).

Most of the industries in developing countries discharge untreated wastewater containing variable concentrations of metals and metalloids into municipal wastewater conveyance systems. Without separation of industrial and domestic wastewater, the wastewater channels carry a blend of industrial and domestic wastewater. Estimates reveal that most untreated industrial-domestic-mix wastewaters contain higher concentrations of chromium, lead, and cadmium than their permissible limits in irrigation water (Murtaza et al., 2010).

Several studies have been carried out to evaluate the implications of wastewater irrigation on the concentrations of metals and metalloids in soils and crops (Qadir et al., 2000; Minhas and Samra, 2004; Lazarova and Bahri, 2005; Hamilton et al., 2007). In a comprehensive sampling program undertaken in two peri-urban areas of Faisalabad, Pakistan, Simmons et al. (2010) quantified the effects of long-term untreated wastewater irrigation on soil quality, wheat yield, and chemical composition of wheat grain and straw. The metal ion concentrations in soils remained below the EU Maximum Permissible Levels for cadmium (Cd), lead (Pb), and zinc (Zn) in sludge-amended soils. In the case of wastewater-irrigated wheat, cadmium and lead concentrations remained below the Permissible Levels for these metals in feed materials. In addition to the studies addressing the impacts of wastewater irrigation on metal ion concentrations in soils and crops, there is a need to regulate heavy metal loads over time as metals and metalloids tend to accumulate in wastewater-irrigated soils. In long-term wastewater irrigation systems, high loads of metal ions may limit crop production. Consequently, the farmers may need to grow plant species that exclude metals, or to use the plants for

Table 2 Distinct groups of selected metal ions based on their bioavailability, phytotoxicity, and risks.

Group	Metal	Soil adsorption	Phytotoxicity and risks
1	Chromium, silver, and titanium	Low solubility and strong retention in soil	Low phytotoxicity and little associated risks as these metals are taken up by plants in negligible concentrations
2	Arsenic, mercury, and lead	Strongly adsorbed by soil colloids	Plant roots may take up these metals but do not translocate to shoots, though elevated arsenic from mixed geogenic-anthropogenic sources has been found in grains. These metals are generally not phytotoxic except at very high concentrations
3	Boron, copper, manganese, nickel, and zinc	Less strongly adsorbed by soil colloids than Groups 1 and 2	Readily taken up by plants and phytotoxic at concentrations that pose little risk to human health
4	Cadmium, cobalt, molybdenum, and selenium	Least adsorbed of all metals	Pose human and animal health risks at plant tissue concentrations that are not generally phytotoxic. Bioaccumulation of these metals occurs through the soil-plant-animal food chain

Modified from Hamilton AJ, Boland A-M, Stevens D, Kelly J, Radcliffe J, Ziehl A, Dillon PJ and Paulin R (2005) Position of the Australian horticultural industry with respect to the use of reclaimed water. *Agricultural Water Management* 71: 181–209.

Fig. 5 Long-term irrigation with untreated or inadequately treated wastewater may lead to absorption of contaminants by crops to elevated levels harmful to the health of humans and animals consuming the crops. Credit: Manzoor Qadir.

other purposes than human and animal food, such as biofuels, ornamental plants, etc. Soil properties such as pH, organic matter and clay content are important to reduce metal mobility and bioavailability.

Based on a survey carried out along the Musi River in India, [Minhas and Samra \(2004\)](#) revealed the transfer of metal ions from wastewater to cows' milk from para grass grown on wastewater-irrigated soil and fed to the animals. The proportion of samples showing excessive amounts of pollutants in para grass samples ranged from 4% for cadmium to 100% for lead. Milk samples were highly contaminated with both metal ions ranging from 1.2 to 40 times higher than the permissible limits. [Qadir et al. \(2000\)](#) found that leafy vegetables irrigated with untreated wastewater accumulated cadmium in greater amounts than non-leafy vegetables on an equivalent mass basis. [Sharma et al. \(2007\)](#) concluded that wastewater irrigation increased the contamination of edible parts of vegetables with cadmium, lead, and nickel resulting in potential long-term health risks. Generally, metal ion concentrations in plant tissue increase with their respective concentration in irrigation water. Concentrations in the roots were usually found to be higher than in the leaves of a range of plant species ([Qadir and Scott, 2010](#)).

Unregulated use of wastewater for irrigation leading to the excessive accumulation of metals and metalloids in soils is detrimental as it is extremely difficult to remove such constituents from soils once they reach the loading limits of certain metals and metalloids ([Fig. 5](#)). Excessive concentrations of metals and metalloids in wastewater-irrigated soils may subsequently cause (1) metal and metalloid toxicity to plants grown on contaminated soils; (2) absorption by crops, resulting in metal and metalloid levels in plant tissues which may be harmful to the health of humans and animals consuming these crops; and (3) leaching of metals and metalloids from soils to groundwater or their accumulation in surface water triggered by surface runoff, thereby rendering the water contaminated and unsafe for other uses ([Murtaza et al., 2010](#)). In relation to groundwater, the use of untreated or inadequately wastewater for surface irrigation may result in leaching of metals and metalloids and other undesirable constituents to groundwater with severe impacts on its quality.

Emerging pollutants

Emerging pollutants refer to any synthetic or naturally occurring chemical or any microorganism that is not commonly monitored in the environment but has the potential to cause known or suspected adverse ecological and/or human health effects ([WWAP, 2017](#)). The changes in living styles and living standards have led to the introduction of a range of such pollutants to wastewater, which consist of but are not limited to endocrine disruptor compounds, hormones, residual pharmaceuticals, drugs, and active residues of personal care products. The presence of such emerging contaminants in wastewater is a matter of growing concern. Such contaminants may have adverse biological effects in animals and humans even at low-level exposures. A range of chemicals have been identified as potential endocrine-disrupting contaminants ([Lu et al., 2020](#)), including industrial contaminants.

Some residual pharmaceuticals and personal care products tend to survive wastewater treatment. Soils irrigated with wastewater containing such contaminants may not hold them resulting in their percolation through the soil to the groundwater. Although many residual pharmaceuticals and personal care products may not be toxic at low concentrations, but they may result in health implications through their effects on the immune and hormonal systems of animals and humans even at low concentrations. There

may be some unspecified toxic effects in the form of rising antibiotic-resistance of bacteria through repeated exposure to antibiotics in wastewater and contaminated streams (Bouwter, 2005).

While the presence of endocrine disrupting chemicals in the environment and the potential ecological consequences are alarming, their concentrations found in the water bodies are usually very low. When they are present in the soil, rapid microbial degradation or adsorption by the soil organic matter occurs. As a result, they may not enter the plant tissue through plant roots in significant concentrations.

The occurrence of many contaminants of emerging concern is often related to discharges from the wastewater treatment plants because of the widespread use of many of these compounds and the lack of technologies with sufficient removal efficiency (Ferreiro et al., 2020). In fact, the legislation related to wastewater treatment (Directive 2000/60/EC, Directive 2008/56/EC, Directive 2013/39/EU) does not yet include many of these compounds. Thus, the wastewater treatment plants remove a part only of such contaminants as the treatment plants are not specifically designed to remove them from wastewater (Prasse et al., 2015; Montes-Grajales et al., 2017). Contaminants of emerging concern have even been found in potable water (Vulliet et al., 2011). Consequently, recent research has focused on avoiding the accumulation of certain contaminants of emerging concern in drinking water.

Chemical stability and slow natural mitigation of certain contaminants makes their remediation a difficult environmental challenge. The degree to which persistent pollutants in wastewater need to be treated depends on (1) pollutant loads, i.e., concentration in wastewater and wastewater volume over time; (2) behavior of these compounds in the soil, which could be assessed through specific bioavailability tests before implementing costly remediation strategies; (3) soil properties, such as soils with large buffering capacities (adequate pH, high soil organic matter content, high cation exchange capacity, medium to deep profile) have greater capacity to filter larger pollutant loads than soils with smaller buffering capacities. For the sites already contaminated with these compounds, the approach usually taken is to isolate the affected sites, and either remove the contaminated soil or rely on phytoremediation (Qadir and Scott, 2010).

In developing countries, the exposure of crops and farmers to organic contaminants is probably higher through pesticide application than organic contaminants in irrigation water. The challenge of any related risk mitigation starts with its assessment, which is costly if based on actual analysis. Thus, such assessments are mostly based on observations (WHO, 2006). An alternative between both extremes may be risk assessment based on easy to monitor environmental factors and application practices (Simmons et al., 2010). More difficult and costly would be the analysis of emerging contaminants, like residual pharmaceuticals or endocrine disruptor compounds (WHO, 2006). A crucial step minimizing the exposure of crops and farmers as well as accumulation of emerging contaminants in soils refers to ensuring separate collection and pertinent treatment of liquid and solid wastes from related industries.

Pathogens

The occurrence of certain viruses, bacteria, protozoa, helminth eggs, and fecal coliforms in wastewater can cause a range of communicable diseases for wastewater-irrigating farmers and traders, and consumers of wastewater-grown food. Such diseases may consist of, but are not limited to, diarrhea, typhoid, dysentery, cholera, gastroenteritis, ascariasis, hepatitis, ulcer, and food poisoning (Grangier et al., 2012; Kesari et al., 2021).

The use of antibiotics for human beings to treat specific diseases has increased over time and it continues to intensify. The use of antibiotics in other sectors such as in poultry and dairy farms and animal production facilities, biochemical industries, and agriculture is common practice, and such use has also increased. Extensive use and/or misuse of antibiotics has resulted in an increase in multi-resistant bacteria, which carry multiple resistance genes (Xu et al., 2017). These multidrug-resistant bacteria collected through the sewerage and wastewater conveyance network end up in the wastewater treatment plants. Thus, it can be inferred that the wastewater treatment plants may serve as a hotspot of antibiotic-resistant bacteria and antibiotic resistance genes. The U.S. Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have already declared that antibiotic-resistant bacteria are an imminent hazard to human health (Kesari et al., 2021).

Among the viruses, coronavirus disease 2019 (COVID-19) in individuals who do not die can damage the lungs, heart, and brain, which increases the risk of long-term health problems. In severe cases, COVID-19 can cause loss of life. One diagnostic near-real-time option that has been highly visible after the pandemic started is detecting the virus causing COVID-19, namely SARS-COV2, in wastewater generated by communities, municipalities, and cities. A big advantage of SARS-COV2 monitoring in wastewater is that it picks up the virus associated with a vast number of people while providing early insights into the transmission trajectory of the virus, e.g., if it is increasing or declining (Larsen and Wigginton, 2020).

Conclusions

While water scarcity is recognized as a key challenge to sustainable development, water-scarce countries and communities need to consider increasingly alternate water resources, such as treated wastewater, to narrow the water demand–supply gap. While the use of treated wastewater needs to be enhanced in water-scarce areas for multiple benefits, large volumes of untreated or inadequately treated wastewater continue to be used for agricultural irrigation in developing countries. Thus, the progress on treatment of

wastewater and fit-for-purpose use of treated wastewater remains slow in most developing countries. Wastewater use for irrigation presents a complex series of tradeoffs, which offer crucial considerations for managing wastewater collection, treatment, and discharge.

The constituents of major concern for environmental risks from untreated or inadequately treated wastewater include excessive concentrations of metals and metalloids, nutrients, salts and specific ionic species, emerging contaminants, and certain viruses, bacteria, protozoa, helminth eggs, and fecal coliforms. The strategies for contaminant risk management have been focused mainly on wastewater treatment options, which have demonstrated positive impacts of safely managed wastewater in agriculture. These should be complemented with farm-based measures that can also play an important role in further minimizing contaminant risk for the environment and human health under situations where untreated or partially treated wastewater is used for irrigation.

There is a need to develop tools and models to evaluate risks from wastewater and implement pertinent risk reduction approaches as a part of the process to assist policy makers in deciding on available treatment options under specific conditions considering environmental, social, and economic dimensions. The right combination of flexible policies, effective institutions, and financial planning and support can help in executing risk management approaches. This is particularly important in areas generating large volumes of untreated wastewater where such interim measures are needed to gradually reach a point when most wastewater would be available in treated form for its safe and productive use.

Abstract

Trace elements may be either essential or toxic to organisms. The most common trace elements in soils are Cd, As, Cr, Hg, Pb, Ni, Zn, and Cu. Pollution of trace elements in soils may be natural or anthropogenic, with the latter including agricultural and industrial sources. Different trace elements pose variable potential risks to ecosystems, food safety and human health. Cadmium and As have low phytotoxicity, and a high risk of soil–food chain transfer posing a threat to food safety and human health, whereas Zn, Ni, Cu, and Cr are ecotoxic at elevated concentrations, thereby posing risks to productivity and functions of ecosystems including C and N cycles.

Key points

- Trace elements enter soils from natural and anthropogenic sources.
- Different trace elements pose different risk pathways to organisms.
- Cadmium and arsenic pose a high risk to food safety and human health.
- Zinc, Ni and Cu are highly toxic at elevated concentrations to ecosystems, threatening ecological functions.

Introduction

A trace element is a chemical element whose concentration (or other measure of amount) is very small (a ‘trace amount’). Some of them are known to be essential micronutrients to soil microorganisms, plants, and or animals, such as iron (Fe), cobalt (Co), copper (Cu), manganese (Mn), nickel (Ni), zinc (Zn), molybdenum (Mo), and selenium (Se). They are essential for metabolic activities at low concentrations, but when they are present at large concentrations exceeding a certain threshold, they are highly toxic to humans and other species. Some are considered to be nonessential (or toxic), such as arsenic (As), cadmium (Cd), lead (Pb), mercury (Hg), and chromium (Cr) (e.g., Cr(VI)) (Table 1; (Rahman and Singh, 2019)). These toxic elements do not have a specific threshold of risk (meaning that it is unclear whether there is any level of exposure that poses no risk to at least some organisms) and are therefore described as the most problematic elements. Even at certain concentrations, these toxic elements can activate resistance of soil bacteria, posing a potential threat to ecological functions.

Both essential and nonessential trace elements occur naturally in soils from geological and pedological processes. Where there is no anthropogenic influence, trace elements are normally present at small concentrations in total or in bioavailable form. They are often immobile and therefore do not pose problems for environmental or human health. In this case, the total concentration of a trace element in soil is called the natural (or geochemical) background value. This value often varies among soils, depending on the mineralogical composition of the soil parent material and on pedogenetic processes (e.g., soil formation). Soils can be polluted due to anthropogenic activities because they are the major sink for trace elements released from agricultural activities (e.g., mineral fertilizers, organic fertilizers including manure and sewage sludge, pesticides, and wastewater irrigation), and rapidly expanding industrial activities (e.g., mining, disposal of wastes, coal combustion residues, and atmospheric deposition) (see references in Wuana and Okieimen (2011)). Unlike organic contaminants, once trace elements have been introduced into soils, they do not undergo microbial or chemical degradation, and thus their total concentration persists for a long time after their introduction.

Table 1 Characteristics of toxic trace elements.

	<i>Arsenic (As)</i>	<i>Cadmium (Cd)</i>	<i>Chromium (Cr)</i>	<i>Mercury (Hg)</i>	<i>Lead (Pb)</i>
Global production (1000 kg year ⁻¹)	36,000–44,000	20,000–24,000	18,000–30,000 × 10 ³	2300	4800 × 10 ³
Abundance in Earth's crust (mg kg ⁻¹)	1.8–2.1	0.15	102–140	0.067–0.085	10.0–14.0
Main valency states in soils	As(III), As(V)	Cd(II)	Cr(III), Cr(VI)	Hg(0), Hg(I), Hg(II)	Pb(II), Pb(IV)
In lithosphere	300+ As-bearing minerals as arsenopyrite (FeAsS), cobaltite (CoAsS), niccolite (NiAs), realgar (AsS), orpiment (As ₂ S ₃), and arsenolite (As ₂ O ₃)	Greenockite and hawleyite (CdS), otavite (CdCO ₃), niedermayrite (Cu ₄ Cd(SO ₄) ₂ (OH) ₆ ·4H ₂ O), and cadmoselite (CdSe)	Ferrochromite (FeCr ₂ O ₄) and crocoite (PbCrO ₄)	Metallic (Hg)(0) or as cinnabar (HgS), corderoite (Hg ₃ S ₂ Cl ₂), and livingstonite (HgSb ₄ S ₈)	100+ Pb-containing minerals as galena (PbS), crocoite (PbCrO ₄), anglesite (PbSO ₄), pyromorphite (Pb ₅ (PO ₄) ₃ Cl), coronadite (PbMn ₈ O ₁₆), and cerussite (PbCO ₃)
Anthropogenic sources	Mining, smelting, combustion of fossil fuels, and production of glass and semiconductors, fertilizers, and chemotherapeutic drug of cancer	Ni–Cd batteries, coatings and platings, stabilizers for plastics, fossil fuel combustion, phosphate fertilizer, waste incineration, mining, ferrous and non-ferrous metal production, and cement production	Tanning, mining, textile dyes manufacturing, wood preservation, metal corrosion inhibition, electroplating, aircraft industry, and cleaning of glassware	Artisanal and small-scale gold mining (ASGM), coal combustion, production of non-ferrous and ferrous metals, cement production, pesticides, and fertilizers	Mining, ore processing, Pb-acid battery recycling (PABC), Pb-containing gasoline in petrol, pipes, ammunition, pesticides, pigment in paints, electronic wastes, dyes, and ceramic glazes
Natural sources	Weathering of rock, microbial colonization, and volcanic eruption	Dust storm, sea salt spray, volcanic activities, weathering, erosion, and wildfire	Tectonic and hydrothermal events	Degassing, weathering of rock, volcanic eruption, and wild fire, and reemission	Natural deposits, natural fires, sea salt spray, and volcanic eruption
Residence time of in atmosphere	7–10 days	Days to weeks	<10 days	~1 year	<10 days
Effect at cellular level	Carcinogenic and neurotoxic	Carcinogenic	Carcinogenic and mutagenic	Neurotoxic	Neurotoxic
ATSDR rank list in priority (2015)	1st	7th	17th	3rd	2th
Pure Earth rank list in priority (2015)	–	6th	5th	3rd	1st

However, it is often the case that some elements undergo changes in chemical forms (i.e., their chemical speciation), which importantly affects their bioavailability, fate, and subsequent risk in soils. Typically, trace elements of anthropogenic origin are generally present in more mobile and bioavailable fractions.

Sources of trace elements in polluted soils

Trace element contents in soils may be influenced strongly by geogenic or anthropogenic inputs and therefore may be long-standing or recently elevated. Pedogenetic processes of weathering of parent materials naturally result in the presence of trace elements at the levels that are regarded as trace or natural background. However, certain types of rocks have particularly large concentrations of trace elements (Table 2; Alloway, 2013) and weathering and pedogenetic processes may cause an increased concentration of some elements in soils. For example, shales generally have larger concentrations of many elements. Trace elements of geogenic origin might be detrimental to human and environmental health. Some endemic diseases are often found in an area where soils have abnormal concentrations of trace elements. For instance, elevated arsenic in drinking water and foodstuffs in some areas have caused endemic chronic poisoning by As (Chen, 2014).

Anthropogenic activities disturb or accelerate nature's slow geochemical cycles of trace elements. As a result, most soils under anthropogenic influences may accumulate one or more trace elements at significantly larger concentrations than the natural background values. This poses risks to ecosystems including plants, microorganisms and soil animals, and threatens the health of animals, humans, or other receptors. Trace elements are defined as 'a pollutant' in the soil environment where (i) the rates of introduction of trace elements into soil from anthropogenic activities are more than natural ones, (ii) via anthropogenic activities, their concentrations are larger than their natural background values, and (iii) trace elements cause adverse effects to soil quality or become transferred to other environmental receptors where the potential for direct exposure or risk are greater. Sometimes, certain trace elements are associated with specific activities, such as irrigation of crops with As-laden groundwater, while many others often result from a wider range of sources through various anthropogenic activities. The main sources of soil pollution can be divided into agricultural sources (i.e., pesticides, mineral and organic fertilizers, wastewater for irrigation, biosolids and manures) and industrial sources (i.e., mining, manufacturing and recycling industries, energy production industries, and air-borne deposition).

Pesticides

Many pesticides used extensively in agriculture and horticulture in the past and currently are sources of trace elements in soils. Of the 1800 active ingredients held in the Compendium of Pesticide Common Names, 219 contain one or more trace elements in their composition (Wood, 2021). Examples of such pesticides are Cu-based fungicidal sprays (e.g., Bordeaux mixture, CuSO₄; copper oxychloride, etc.) that are applied in vineyards and orchards. Fungicides and pesticides containing As, Cu, Mn, and Zn were used historically to protect citrus (*Citrus* spp), apples (*Malus domestica* Borkh.), peaches (*Prunus persica*), strawberries (*Fragaria x ananassa* Duchesne), and other fruit crops. Lead arsenate (AsHO₄Pb) was used in fruit orchards for many years to control parasitic insects (Alva, 1992). Organomercury compounds such as phenylmercury acetate were used as seed dressings (Byford, 1985). Chromated copper arsenate was used as a wood preservative (Hingston et al., 2001). Arsenic-containing compounds (e.g., monosodium methyl arsenate, MSMA) were also used extensively to control pests and control weeds (Matteson et al., 2014). Such applications can potentially cause soil pollution. This problem is of particular concern when contaminated soils are used for food production. With the growing awareness of risk to environmental and human health posed by pesticides, many that contain hazardous chemicals including trace elements have been banned for use. Soil pollution associated with pesticides is often local and restricted to particular sites or crops.

Fertilizers

Plants require not only macronutrients (e.g., N (nitrogen), P (phosphorus), K (potassium), S (sulfur), Ca (calcium), and Mg (magnesium)), but also essential micronutrients. These nutrients can come naturally from the soils themselves through the dissolution of minerals, desorption from minerals, decomposition of organic matter, and other processes. Some soils are deficient in essential micronutrients for plant growth and crops must be supplied with them to increase crop production. An example of such is if cereal crops are grown on Zn-deficient soils they are occasionally treated with Zn as an addition to the soil or as a foliar spray. In addition, large quantities of N, P, K fertilizers and organic fertilizers are regularly applied to soils in intensive farming systems to increase crop production. Phosphorus fertilizers are a major source of Cd in agricultural soils because they often contain relatively large concentrations of Cd that is naturally present in the raw material used (i.e., phosphate rock) for P fertilizer production (McLaughlin et al., 2021). Approximately 85% of global P fertilizer production is from sedimentary deposits in which average Cd content is about 69-fold higher than that of non-phosphate containing rocks (Van Kauwenbergh, 2010). Numerous long-term field studies have observed that continuous use of phosphatic fertilizers inadvertently increased Cd concentrations in soils in the U.S., Canada, Australia, New Zealand, and EU (European Union) countries (McLaughlin et al., 2021). Inevitably, repeated applications of high rates of P fertilizers containing large concentrations of Cd increased those of phytoavailable Cd in soils and crop Cd concentrations. Soil Cd concentrations in relation to P fertilization depend on the balance between Cd input and Cd removal over time (Fig. 1; Salmanzadeh et al., 2017). A reduction in Cd concentration in P fertilizer can reduce the increase in soil Cd concentration.

Organic manures (animal manures, compost, and sewage sludge)

Solid residues after treatment of municipal sewage sludge (biosolids), livestock manures and composts, are a valuable source of macronutrients, micronutrients as well as organic matter. The application of such organic manures can improve fertility and physicochemical properties in agricultural soils through organic carbon enrichment and the slow release of nutrients. Their application is a common practice in many countries and is also the cheapest way of recycling or disposal. In the United States, more than half of approximately 5.6×10^8 kg dry sewage sludge is applied to land annually across the country (Silveira et al., 2003). Similarly, in the European community over 30% of the sewage sludge is used as fertilizer in agriculture, and in Australia, most of the dry biosolids produced each year (over 17.5×10^6 kg) are applied to agricultural land (Silveira et al., 2003).

Organic manures also contain trace elements, leading to the accumulation of these metals in soils, e.g. As, Cd, Cu, Pb, Hg, Ni, Zn, etc. In intensive livestock production, for example, the feeds may contain essential trace elements such as Cu and Ni, and toxic trace elements such as Cr, Pb, and As. The incorporation of metals such as Cu and Zn into animal feeds is a common practice, because they can improve production efficiency. It has been reported that concentrations of some trace elements in manures increased greatly from 1990 to 2020 (Wang et al., 2014; Zhang et al., 2012). Copper sulfate, as a footbath, is often used to treat lameness in dairy cattle and also used as a widespread growth promoter in pig and poultry systems (Xiong et al., 2010). Zinc oxide is added to pig feed as a cure for diarrhea (Poulsen, 1998). Roxarsone is an arsenic-containing compound widely used as a feed additive in poultry industries to control coccidiosis and promote growth (Chapman and Johnson, 2002). These applications in the animal feed result in larger concentrations of trace elements in manures. This may potentially cause soil pollution if the manures produced from

Fig. 1 The mean concentrations of Cd in topsoil samples from Winchmore research farm on the Canterbury Plains of the South Island, New Zealand, over the period 1959–2015 related to Cd-containing P fertilizers. The concentration of Cd in fertilizer has decreased since the 1980s. From Salmanzadeh M, Hartland A, Stirling CH, Balks MR, Schipper LA, Joshi C, and George E (2017) Isotope tracing of long-term cadmium fluxes in an agricultural soil. *Environmental Science & Technology* with permission.

animals on such diets are continuously applied to agricultural land. Under certain conditions, trace elements introduced to soils through applications of biosolids can be leached downwards through the soil profile and can potentially pollute groundwater (Gianico et al., 2021).

Wastewater for irrigation

Worldwide, approximately 20 million hectares of arable land are irrigated with wastewater in developing countries, especially in or close to cities, where it is plentiful (Scott et al., 2004). The types and concentrations of trace elements in the wastewater depend on the sources of effluents and the technologies used to treat them (Scott et al., 2004). Wastewater has been widely used for irrigation in agriculture, especially in developing countries. A few countries have reported the direct use of untreated wastewater for irrigation, and for example the volume reaches 4 million cubic meters per year in Mexico. Although wastewater provides low-cost resources for irrigation, irrigation with untreated wastewater can contribute to the accumulation of trace elements, and organic contaminants such as persistent organic pollutants (POPs) and perfluoroalkyl and polyfluoroalkyl substances (PFAS), as well as a source of dangerous pathogens, and pharmaceuticals and personal care products in soils (Islam et al., 2018). Crops irrigated with untreated wastewater can potentially accumulate toxic trace elements in their edible parts at an elevated concentration which pose risks to human health.

Mining processes

Mining is a potential major source of trace elements in soils, not just from the mining operation itself, but mostly from wastes and emissions during the processing of the extracted materials such as in tailings, waste rock deposit, and from smelting operations (Table 3) (FAO and UNEP, 2021). Mining waste often contains one or more trace elements at concentrations at which extraction is not cost effective, but they may still pose a risk to the environment and human health. Mining to exploit coal, gold (Au), uranium (U), tungsten (W), tin (Sn), platinoids and polymetallic sulfides, have caused the most severe cases of soil pollution, according to the reports by the FAO and ITPS (FAO and ITPS, 2015). Mercury is often used for the extraction of gold and consequently gold mining operations often result in the emission of mercury. It is estimated that large-scale gold mining is responsible for about 2.7×10^6 kg of mercury entering the soil each year (UNEP, 2019). Tailings are made of water and fine mineral particulates and are often constructed on site by means of a dam. They may cause soil pollution when the tailings dam fails or from wind erosion that disperses the fine mineral particulates from the surface. This often leads to soil pollution of areas at long distances from the sources. There have been many accidents involving ruptures of tailings dams historically, releasing toxic waste rich in As, Cd, Cu, Pb, and Zn that then accumulated in soils or reached surface waters. In addition, extensive Pb and Zn ore mining and smelting have often resulted in soil pollution from water or wind erosion of deposits of ore and rock waste (Hu et al., 2019). Where mining wastes that contain reduced sulfur minerals (e.g., pyrites) are exposed to oxygen and water, acid mine drainage (AMD) tends to form. This can lead to the formation of large volumes of highly acidic wastewaters containing large concentrations of sulfates, iron, and trace elements. In the event of a leakage, AMD could lead to the pollution of water bodies and subsequent transfer to soil. Spillage during the transfer and transport of ore concentrates to the smelter is another potential source of soil pollution. Particulate and gaseous emissions from a smelter that lacks appropriate control technologies are a local and long-distance source of trace elements to soils. For instance, worldwide 85–90% of total atmospheric Cd emissions arise from anthropogenic sources and most of the Cd in the atmosphere is associated with suspended particulate matter (aerosols) in the form of oxides, sulfates, and chlorides (McLaughlin et al., 2021). In Europe, Cd emissions decreased markedly from 2500 Mg year⁻¹ in the 1960s to 68–191 Mg year⁻¹ between 1990 and 2017 with the installation of more efficient flue gas desulfurization equipment in smelters and power plants (McLaughlin et al., 2021). This downward trend in atmospheric Cd concentrations have caused a marked decrease in deposition of Cd into soils.

Table 3 Trace elements likely to occur in soils in contaminated environments.

Trace elements	Industrial sources
Antimony (Sb)	Electronics, metal smelting
Arsenic (As)	Insecticide manufacture and use, wood preservation
Beryllium (Be)	Nuclear, munitions, and electronics
Cadmium (Cd)	Pigments, alloys, electroplating, batteries, mining, and smelting industries
Chromium (Cr)	Plating, tanning, inks, wood treatment, pigments, and dyes
Copper (Cu)	Mining and smelting, wood treatment, electronics, plumbing, copper and brass manufacture
Lead (Pb)	Batteries, tetraethyl lead production, mining, smelting, plumbing
Mercury (Hg)	Chemical plant, mining and smelting, refining gold and silver, electrolysis industry, chlor-alkali plant, paper mills
Nickel (Ni)	Plating and metal works, batteries, iron and steel industries, electronics
Selenium (Se)	Smelting, paint, pigment, electronics
Silver (Ag)	Mining, photographic, electroplating, silver manufacture
Thallium (Tl)	Cement industry, electronics
Zinc (Zn)	Mining and smelting, plating, galvanizing, runoff from galvanized surfaces, print and paper

Manufacturing and recycling industries

The textile industry may also release toxic trace elements in effluents. Large amounts of wastewater, produced in the dyeing and finishing process often contain trace elements including As, Cd, Co, Cu, Pb, Hg, and Ni (Table 3). Leather manufacture and tanneries produce large amounts of solid and liquid by-products including Cr(III) compounds, thus tannery effluents are highly enriched in Cr (Alvarez-Bernal et al., 2006). During the process, Cr(III) can be oxidized to its much more toxic hexavalent state (chromate, Cr(VI)). The tanning process has caused many cases of Cr pollution in soils. Soil pollution by chromate-containing tanning effluents may contaminate water bodies or underground waters because of the greater mobility of chromate than trivalent chromium.

The manufacturing and recycling of Pb-acid and Ni-Cd batteries are important sources of trace element pollution in soils (McLaughlin et al., 2021). About 25,000 Mg of Cd were produced in 2017 of which 80% of the Cd produced was used for the manufacture of batteries (U.S. Geological Survey, 2019). The manufacturing of Pb-acid batteries consumes about 85% of Pb worldwide and is growing, especially in the Asian market with the rapid development of industries that use Pb-acid batteries such as electric bikes, electric power vehicles, and photovoltaic devices. Pollution occurs during the production and recycling of batteries when factories lack proper pollution control and regulatory oversight. For example, the production of Pb-acid batteries can generate and release fine Pb dust through atmospheric dispersion, leading to its deposition on soils (FAO and UNEP, 2021). For example, a survey from lead battery manufacturing and recycling in seven African countries has demonstrated that lead concentrations were 26,000 mg kg⁻¹ in soils surrounding the plants, posing significant health risks to the public (Gottesfeld et al., 2018).

Energy production industries

Coal-based energy production generates a large volume of wastes, including fly ash, bottom ash, boiler slag, and flue gas. Coal wastes in landfills and surface impoundment ponds often result in frequent leaching and exposure of materials to weathering and erosion due to the lack of adequate pollution control measures. There are many examples of polluted soils around coal waste deposits. Coal fly ash contains silicon, aluminum and trace elements such as Cd, As, Cu, Hg, and other organic contaminants such as PAHs (polycyclic aromatic hydrocarbons). The concentrations of trace elements vary with the type of coal and are often found to be positively correlated with sulfur concentrations (FAO and UNEP, 2021). Atmospheric deposition from coal combustion is an important pathway by which trace elements accumulate in soils (Bian et al., 2009). Coal combustion largely contributes mercury emissions to the soil, mainly through airborne particulates. Some trace metals such as As, Cd, Pb can also volatilize during high-temperature processing and then convert to oxides and condense as fine particulates (Wuana and Okieimen, 2011). The airborne particulates are eventually deposited on land or water bodies and thus most forms of fossil fuels are an important form of soil pollution. For example, 85–90% of total atmospheric Cd emissions globally arise mainly from fossil fuel combustion, nonferrous metal manufacturing, iron and steel production, cement production, and waste incineration; they are an important source of soil pollution (WHO, 2011).

Characteristics of trace elements in soils and potential risk pathways

Trace elements are commonly found in polluted soils, with most reports being for Cd, As, Cr, Hg, Pb, Ni, Zn, and Cu. Soil pollution with potentially toxic trace elements may pose risks and hazards to ecosystems, food safety, and humans through many pathways, depending on the basic chemistry of the trace elements (Table 4 and Fig. 2). The ecotoxicological effects and risks of trace elements not only depend upon their total concentrations in soils, but also upon their bioavailability. The concept of a 'soil–plant barrier' (Chaney, 1980; Zhao and Wang, 2020), proposed to describe the ability of trace elements to enter the food chain, can be used to divide trace elements into four categories. The first category has very low solubility in the soil so that their bioavailability to plants is also very low; these elements include Pb, Hg and Cr(III). The second category is those elements that can be strongly sorbed on root surfaces or strongly chelated in the root cells so that their translocation to other parts of the plant is very limited; elements such as Hg and Pb. The third category can cause phytotoxicity and decrease crop production, and so the damaged crops are less likely

Table 4 Critical risk pathways of trace elements.

<i>Risk Pathways</i>	<i>Potential trace elements</i>	<i>Risk</i>
Soil → Plant	Zn, Cu, Ni, etc.	Ecosystem
Soil → Micro- or Macroorganism	Zn, Cu, Ni, etc.	Ecosystem
Soil → Plant → Human	Cd, As, MeHg	Human health
Soil → Plant → Animal → Human	Cd, As, MeHg	Human health
Soil → Underground water → Human	Cr(VI), As	Underground water
Soil → Oral, Skin → Human	Pb	Human health

Fig. 2 Soil-plant barriers and the risk of toxic element transfer to the food chain in the paddy rice system.

to be consumed by humans or domestic animals; elements include Cu, Zn, Ni and As. The fourth category has relatively strong solubility in soils and high translocation in plants and causes toxicity to humans at levels that do not cause phytotoxicity; the elements include Cd, selenium (Se), molybdenum (Mo) and As. However, Se and Mo rarely cause toxicity and in contrast, their deficiencies in animals and humans are the more common. Cadmium is the most important toxic trace metal threatening global food safety through the soil to the food chain (McLaughlin et al., 2021). Arsenic also has a high risk of soil-food chain transfer in paddy rice systems, a worldwide concern threatening rice production and food safety (Meharg et al., 2009; Meharg and Zhao, 2012). Rice is the most important contributor to dietary Cd and As intake and sometimes methylmercury (MeHg, CH_3Hg^+) (see references in Zhao et al. (2022)).

In view of the risk to human health associated from soil pollution, the critical pathways include direct ingestion or contact with contaminated soil (e.g. Pb; soil-oral, skin), the food chain (e.g. Cd, As and MeHg; soil-plant-human or soil-plant-animal-human), drinking of contaminated groundwater (e.g. Cr(VI), As), and reduction in soil functions or quality through ecotoxicity (e.g. Zn, Cu, Ni, etc.) (Table 4).

Summary

Trace elements, including essential and toxic elements, occur naturally in soils related to geological and pedological processes. Anthropogenic activities disturb or accelerate the accumulation of trace elements in soils, resulting in soil pollution. Sources of trace elements that lead to soil pollution are very varied and range from various agricultural sources to industrial activities. To prevent and reduce soil pollution with trace elements, great effort should be made to reduce the emission of trace elements into soils by reducing the production and use of toxic trace elements in agricultural activities, and in minimizing emissions from industries or by shifting industrial production toward more sustainable systems in which the emissions are reduced. Trace elements differ largely in their potential to pose risks to ecosystems, food safety, and humans. To reduce soil pollution by trace elements, prevention is the first and foremost action against pollution. Scientifically, further research is needed to fill knowledge gaps in the pollution cycle. Legislative actions and monitoring networks are also required to be strengthened. Finally, public awareness and communication should be improved.

Abstract

Pollution can lead to disease and premature death in the world today. In 2015, about half a million deaths were estimated to be associated with soil pollution. Many organic pollutants can persist in the soil environment for a long time and are referred to as persistent organic pollutants (POPs). This chapter provides an overview of how the chemical properties and fundamental processes of conventional POPs (e.g., polyaromatic hydrocarbons, polybrominated diphenyl ethers) as well as new POPs (e.g., Per- and Poly-fluoro Alkyl Substances—PFAS) control their fate and behavior in the soil environment and determine their potential impact on biota.

Key points

- The environmental burden of persistent organic pollutants (POPs) is growing.
- Per- and Poly-fluoro Alkyl Substances (PFAS) are new POPs that are now ubiquitous in the environment.
- PFAS have markedly different properties from conventional POPs (e.g., PAHs, PBDEs) and many PFAS being hydrophilic are more mobile than the conventional POPs in the environment.
- The conventional approaches to assess fate and behavior of POPs (e.g., models based on octanol: water partition coefficient $-K_{ow}$) do not apply to PFAS and need to be refined.
- Currently, the fate and behavior of PFAS in the soil environment is poorly understood.

Introduction

"Pollution is the largest environmental cause of disease and premature death in the world today", according to The Lancet Commission on Pollution and Health (Lancet, 2018). In 2015, about half a million deaths were estimated to be associated with soil pollution. Deaths caused by pollution tend to be disproportionately higher in low- to middle-income countries, as well as among minorities and marginalized sections of society.

Organic pollutants are ubiquitous in the environment and their environmental burden is continuously growing, largely because of anthropogenic activities and the synthesis of myriad chemicals over last two centuries. A wide range of organic chemicals in industry, such as polyaromatic hydrocarbons, flame retardants, pesticides can find their way to the soil environment after their use.

Soil can be a major sink for many of the organic pollutants released into the environment. These compounds enter the environment through a wide variety of processes including inefficient combustion, dry and wet deposition from the atmosphere, widespread pesticide use, and wastewater drainage from industrial and domestic sources into sewers or directly into the soil environment. Once in a soil, high-molecular-weight non-ionic organic compounds may persist for decades.

Many organic pollutants can persist in the soil environment for a long time (e.g., the pesticide DDT is still detected in soil environment despite its widespread application was stopped some 40 years ago) due either to their inherent chemical properties not favoring degradation (e.g., strength of the chemical bonds) or to their binding to the soil solid phase (organic and mineral matter). Strong binding and sequestration can protect them from breakdown by soil microorganisms. These persistent chemicals are generally referred to as persistent organic pollutants (POPs).

Soil POPs are potentially bioavailable to many organisms, including soil microflora, macrofauna (e.g., earthworms), plants, animals and humans (Jones, 2021). Soil POPs may be taken up by plants and other organisms, enter the food chain and thus impact human and ecosystem health. Therefore, the bioavailability of POPs to organisms is important in determining the potential hazard presented by a soil contaminated by POPs. Their mobility and bioavailability may also influence the effectiveness of soil remediation measures.

A range of properties of chemicals (e.g., hydrophobicity, electrostatic charge, volatility) control their distribution among, and impact on, various environmental compartments. Several fundamental processes (e.g., sorption and desorption) governing the distribution of POPs among the various phases of the soil (i.e., solid-, air- and aqueous-phase) determine their mobility, bioavailability and potential environmental impact.

This chapter provides an overview of how the chemical properties of conventional POPs (e.g., polyaromatic hydrocarbons, organochlorine pesticides) and new POPs (e.g., Per- and Poly-fluoro Alkyl Substances—PFAS) control their fate and behavior in the soil environment. Being so unique in their properties, PFAS are being discussed separately, where appropriate, as new POPs.

The chapter draws heavily from the previous version by D. Johnson (Rothamsted Research, Harpenden, United Kingdom) published in the first edition of this Encyclopedia (Johnson, 2005). The original article has now been updated with a new class of POPs, namely the Per- and Poly-fluoro Alkyl Substances (PFAS) due to their extreme persistence and bioaccumulation. Some PFAS (PFOS and PFOA) have already been added to the Stockholm Convention List of POPs.

Persistent organic pollutants (the conventional and new POPs)

Since the 19th century, humans have produced and released vast quantities of organic compounds into the biosphere. These compounds are widely distributed throughout the environment and many are considered carcinogenic and mutagenic. This has led to the prioritization of organic pollutants by the United States Environmental Protection Agency (USEPA) and the European Community (EC). These lists include polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs), chlorobenzenes (CBs), phthalate acid esters, pesticides and other miscellaneous compounds. Many members of these classes of chemicals are extremely persistent. According to the Stockholm Convention on Persistent Organic Pollutants (POPs), the “POPs are organic compounds that are resistant to environmental degradation through chemical, biological, and photolytic processes”. The Stockholm Convention is an international treaty to protect human health and the environment from POPs.

In 2001, a group of 12 chemicals were identified as POPs (the initial POPs). However, in 2009 it was decided to add 16 new chemicals to this list. These included some chemicals used as pesticides (e.g., Lindane, Endosulfan), flame retardants (some polybrominated diphenyl ethers—PBDEs), and as water repellents and fire-fighting foams (e.g., perfluorooctane sulfonic acid—PFOS). The current list of all POPs plus information on their use, production and replacement options is available at the Stockholm Convention’s website (the link is provided at the end of this chapter). Among these, the per- and poly-fluoroalkyl substances (PFAS) are a large group of chemicals which are quite unique in their chemistry and are very different from the original POPs identified in 2001.

The PFAS have emerged during the last decade as one of the major soil pollutants around the globe (Wang et al., 2017). According to OECD, nearly 5000 chemicals belong to PFAS family; however, only 256 of these are currently commercially relevant (Buck et al., 2021). Many PFAS are considered both extremely persistent and extremely mobile in the soil environment (e.g., anionic or ionizable PFAS). Their high mobility and extreme persistence together lead to their ubiquitous presence in soil and water and potential exposure to humans and wildlife. Some PFAS, such as PFOS, PFOA, PFHxS (and their salts and associated substances) have either been placed on the Stockholm Convention list of priority pollutants (A, B or C) or are under consideration for such classification. Agreement on phasing out of PFOS and PFOA (where possible) has already been reached under the Stockholm Convention in 2009 and 2019, respectively. However, alternatives are currently not available for some of the products containing PFOS and PFOA.

Conventional POPs

A majority of POPs (e.g., PAHs, PCBs, PCDD/Fs, CBs and organochlorine pesticides such as DDT, dieldrin, heptachlor, hexachlorobenzene) are hydrophobic in nature. They are characterized by their relatively high octanol/water partition coefficient ($\log K_{ow}$) and low water solubility. Thus, once in a soil they tend to be resistant to microbial degradation and prone to bioaccumulation. Atmospheric transport processes such as 'global distillation' result in an almost ubiquitous contamination of soils, often thousands of kilometers from major POP sources. The highest soil concentrations of POPs are usually found near industrial point sources, urban areas, and in organic-rich soils, as POPs tend to accumulate in organic matter. The disused sites in the manufacturing industry in many western economies have left large areas of soil contaminated by such POPs and requiring remediation before they can be re-developed.

New POPs (PFAS)

Since commencement of their production in the 1950s, PFAS have been extensively used in a range of industrial (e.g., production of Gore-Tex™, Teflon™, electronic goods, metal plating) and commercial applications (e.g., stain- and water-resistant textiles, food packaging) as well as in military training activities (e.g., in fire-fighting). The PFAS class also includes polymers (PTFE or Teflon™) which are also used in stain- and water-resistant textiles and food packaging. The non-polymer surfactant PFAS are used as aqueous film-forming foams (AFFFs) to extinguish fires and are more abundant in the environment, due to their regular use at airports and defence facilities, for example. Consequently, PFAS are now ubiquitous in various environmental compartments, such as soil and water, including in oceans (Krafft and Riess, 2015a; Krafft and Riess, 2015b), and have been found to bioaccumulate and biomagnify (Giesy and Kannan, 2001). The accumulation of PFAS in soils reported from various countries is apparent from the data compiled in Table 1 (Brusseau et al., 2020).

The PFASs generally have a hydrophobic 'tail' that contains a high proportion of fluorine (C—F chain), a hydrophilic functional group (e.g., carboxylate, sulfonate) and in many cases a 'spacer' organic group linking these two portions of the compound together. Replacing the hydrogen atoms (in a hydrocarbon chain in organic molecules) by fluorine atoms allowed a range of unique chemical properties that enabled this group of chemicals to be used for a diverse range of functions and applications mentioned above (Krafft and Riess, 2015a).

Physicochemical properties of POPs in soils

Conventional POPs

The principal conventional POPs found in soils are PAHs, PCBs, CBs, and PCDD/Fs. Table 2a displays comparative physicochemical data for several selected POPs that occur in contaminated soils. Clearly, these compounds are highly hydrophobic in nature (high values of $\log K_{ow}$) and consequently they readily partition onto the soil organic carbon (OC) phase. Therefore, their sorption or partition coefficient (K_d) in soils is often normalized against the fraction of OC in soils (i.e., $K_{oc} = K_d/\text{fraction of OC}$). The $\log K_{oc}$ values in Table 2a show a strong correlation with their K_{ow} values.

Table 1 Per- and poly-fluoro alkyl substances (PFAS) concentrations reported in soil at primary-source contaminated sites in various countries.

Locations	Type of site (number of sites)	Maximum PFOS ^a Concentration $\mu\text{g kg}^{-1}$	Maximum PFOA ^a Concentration $\mu\text{g kg}^{-1}$
Australia	Airports (6)	84,200	6400
	Fire training area (unspecified)	460,000	3200
Belgium	PFAS manufacturing (1)	7800	114
Canada	Crash site (1)	9.3	29
China	PFAS manufacturing (1)	2583	50
	PFAS Industrial Park (1)	0.4	5.3
Norway	Fire training area (4)	8924	141
	Fire training area (6 airports)	17,400	75
Sweden	Fire training area (4)	8520	219
United States	Fire training area (1)	36,534	11,484
	AFFF ^b Source Zones (10 military installations)	9700	58
	AFFF Source Zones (Many military installations)	373,000	50,000
Global	Median	8722	83
Background level	Median	2.7	2.7

New POPs (PFAS)

The PFAS, a large group of substances (polymers and non-polymers) including solids, liquids and gases, have a broad range of physical, chemical and biological properties (Buck et al., 2021). The chemical properties of PFAS are very different from those of conventional POPs (Table 2b). The PFAS are aliphatic substances characterized by a partially or fully fluorinated alkyl chain and a functional head-group (such as carboxylates, sulfonates, sulfonamides, phosphonates and alcohols) (Buck et al., 2021). Properties of these chemicals include their exceptional thermal and chemical stability—attributable to the strength of the C—F bond in the fluoroalkyl tail, stronger polarization and greater hydrophobicity than alkyl chains of comparable length. The addition of functional head-groups increases their water solubility. Consequently, the functionalized fluorochemical has surfactant properties because of both hydrophobic and hydrophilic moieties (Krafft and Riess, 2015a). The key features of fluorinated surfactants include their

surface activity in both aqueous and organic solvent systems, reduced surface tension, which results in superior wetting, spreading, and levelling properties on all types of surfaces, effective emulsification in specialty applications, and extreme stability both chemically and thermally (Krafft and Riess, 2015a).

The PFAS are unique due to the properties of the C—F bond, with high electronegativity and polarity (Krafft and Riess, 2015a). Therefore, many of the PFAS compounds (e.g., carboxylates and sulfonates) are present in the anionic form over the environmentally relevant pH range (4–9). These PFAS are highly water-soluble and consequently have a high mobility in the environment. The most common detections in wastewater treatment, fresh water and ground water systems have been of anionic PFAS such as perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA). The acidic head-group makes them hydrophilic, whereas the tail made of the C—F chain makes them hydrophobic and consequently their partitioning properties also depend on the length of the C—F chain (Table 2b). On the other hand, several PFAS contain amide and sulfonamido head-groups and are cationic in nature. Furthermore, some PFAS (e.g., fluorotelomer sulfonamido alkylbetaines, FTABs) are zwitterionic. For example, perfluorooctane amidoalkyl betaine (PFOAB) contains other ionizable functional groups in addition to a positive charge in its structure ($-N^+(CH_3)^2-$); this theoretically results in four species with different charges. Clearly, PFAS have more complex chemistries than conventional POPs.

Fate and behavior of POPs in the soil environment

Legislation relating to organic compounds in soil is largely based on toxicological criteria with the aim of protecting wildlife and human health. Thus, it is important that the ‘availability’ of compounds to transfer from the soil to organisms is understood in a quantitative manner. Recent research on the fate and behavior of organic chemicals in soils suggests that the availability of an organic compound from the soil into the food chain may depend markedly on the form in which a compound is present in a soil and how it has interacted with the soil solid-phase. This is influenced by several factors, including its residence time within the soil, physicochemical properties of the compound and soil, and how it entered the soil. Desorption of sorbed compounds into the soil solution enhances biodegradation, leaching, volatilization, plant uptake and other chemical or photochemical transformations. Whilst these processes are generally enhanced by the chemical being present in the bulk soil solution, chemical degradation, photochemical transformations and biodegradation of soil-sorbed compounds are also possible. Furthermore, soil-sorbed compounds may also be lost from areas of soil by wind and water erosion, uptake by invertebrates or direct ingestion of soil by grazing livestock.

Persistence of organic chemicals in soils

The persistence and relative significance of each loss pathway in a soil depends on the physicochemical properties of the organic chemical and environmental conditions. However, regardless of the main loss pathway, the overall loss of organic chemicals from soils is often biphasic. This means that a short period of rapid initial loss is most often followed by a longer period of slow dissipation. Loss processes in soils exhibit similar patterns. The primary rate-limiting factors governing this biphasic behavior are thought to be fundamental sorption or desorption mechanisms that control the distribution of a chemical between the solid and aqueous or gaseous phases of soil and hence, the supply of chemicals available to the various loss pathways. The availability of organic compounds in a soil will affect both the toxicological threat and the potential to remediate a contaminated site. Further details relating to specific technologies available for contaminated soils can be found in the chapter on the remediation of polluted soils.

Conventional POPs

The persistence and overall loss of organic chemicals from soils following their entry into a soil depend on the physicochemical properties of the soil and the chemicals themselves, environmental factors, including temperature and precipitation, and anthropogenic factors such as cultivation and drainage.

Typically, organic contaminants with short half-lives exhibit relatively rapid dissipation with most of the residues ultimately being removed from the soil. Such decay curves are typical of compounds that are volatile, water-soluble, or easily degraded (or a combination of these). Examples of this type of chemical are the lighter chlorinated benzenes and volatile aromatic hydrocarbons. At the other extreme, chemicals that are nonvolatile, relatively water-insoluble and recalcitrant, dissipate slowly. Such chemicals are strongly sorbed and persist in soils over often extremely long periods. Examples include PCDDs and PCDFs. Most organic compounds fall within these two extremes, with an initial period of rapid loss followed by a much slower dissipation of the chemical. This leads to a ‘persistent residual fraction’ of the compound forming in the soil, the size of which will be determined largely by the physicochemical properties of the compound and soil. As mentioned earlier, a loss profile of this shape is often referred to as ‘biphasic’ and is typical of organic chemicals with intermediate sorption potentials.

New POPs (PFAS)

The chemical structure of PFAS contains the C—F bond, the strongest covalent bond known in organic chemistry (Krafft and Riess, 2015a). The small size and unique properties of fluorine make the PFAS thermally and chemically stable. Therefore, per-fluorinated compounds, PFAS, which are fully fluorinated (e.g., PFOS, PFOA) are extremely persistent. On the other hand, the poly-fluorinated

compounds, which also contain hydrocarbon (C—H) or other non-fluorinated bonds (e.g., C—H or C—O) in the structure, are susceptible to biotic or abiotic breakdown and transformations (similar to conventional POPs). However, the breakdown of the polyfluorinated compounds often leads to a transformation into shorter chain perfluorinated compounds as terminal degradation products, and therefore, are considered as potential precursor compounds. The degradation process also produces transient degradation intermediates that may persist in the soil environment. Examples of such transformation include degradation of fluorotelomer alcohols (FTOH) or fluorotelomer sulfonamido alkylbetaines (FTABs—see Table 2b) into intermediate PFAS as well as terminal perfluoroalkyl carboxylates of various chain lengths (e.g., PFOA). Several studies on soils, sediments and sludges (reviewed by Butt et al., 2013) have shown that breakdown or transformation of 6:2 FTOH and 8:2 FTOH through biotic and abiotic pathways could result in the formation of terminal perfluoroalkyl substances such as PFOA, PFHxA (typical yields of 1–2%) and several (5–12) intermediate metabolites (both transient and terminal) some of which may be covalently bound to biological macromolecules and thus become non-extractable (making up to 10–35% of the original mass). In terms of the processes of ‘ageing’ and formation of bound residues, discussed below, there may be commonality between these intermediate products and the conventional POPs. However, more work is needed to understand this phenomenon fully for PFAS.

The ‘ageing’ of POPs within soils

As discussed above and can be seen in Fig. 1, when an organic compound enters a soil, it undergoes a number of loss processes including leaching, volatilization, chemical and biological degradation, and plant uptake. In addition, sorption- and transport-related processes mean that an increasing component of the soil-borne compound becomes ‘irreversibly bound’ within the soil matrix, i.e., it cannot be extracted by conventional analytical techniques. The result is that, as the residence times of organic compounds increase within a soil, they become increasingly difficult to extract. This phenomenon has become known as the ‘ageing effect.’ There is also an assumption that there is an analogous decline in a compound’s bioavailability as soil residence time increases and extraction efficiency declines, but this may be erroneous (see later).

Fig. 1 demonstrates that this process of declining extractability of soil-bound compounds is, in part, due to the formation of irreversibly bound residues within the soil matrix. The development of irreversibly bound residues is a major contributing factor in the formation of persistent residual fractions of organic chemicals in soils. Addressing this issue is complicated by the fact that experimental data are highly dependent on the extraction method used and knowledge that the efficiency of extraction of an organic chemical from a soil will decline with increasing contact time between a chemical and the soil, i.e., the ‘ageing effect.’

Several groups of mechanisms are thought to be involved in the ‘ageing effect’ of organic chemicals in general, including POPs. The processes involved can be split into transport-related and sorption-related mechanisms. Transport-related mechanisms are those where sorption or desorption of organic chemicals is controlled by water flow in soils, especially in structured soils, where, for example, a network of cracks may develop due to swelling and shrinkage of soils, leading to mobile and immobile domains for chemical transport.

Sorption-related mechanisms

Sorption mechanisms of conventional POPs can be divided into two distinct classes: diffusive mass transfer and chemisorption. Diffusive mass transfer mechanisms include film diffusion, pore diffusion, retarded intraparticle diffusion, and intraorganic matter diffusion. Film diffusion relates to the resistance encountered by an organic chemical when crossing a thin film of water surrounding soil solids or aggregates, or when moving from the solid phase into the bulk solution or gaseous phases. Depending

Fig. 1 Dynamics of organic chemical persistence, bioavailability and loss in soils. After Johnson D (2005) Pollutants/persistent organic (POPs). In: Hillel D (ed.) *Encyclopedia of Soils in the Environment*, pp. 264–271. Elsevier.

on the nature of sorbents and sorbate (within soil, i.e., organic matter, inorganic minerals), the sorption process may involve various stages: (i) film diffusion across the liquid film surrounding the external surfaces of soil particles, (ii) intraparticle diffusion into the liquid in the pores and along the pore walls and (iii) slower phase of sorption.

Chemisorption occurs when a functional group of an organic chemical interacts with reactive moieties on soil solids through the formation of strong chemical bonds, principally covalent bonds. Such interactions give rise to the formation of a fraction that is irreversibly sorbed, despite exhaustive extraction procedures, and has become known as 'bound residues' in the area of pesticide science. However, pesticides are often ionic, in contrast to nonionic compounds such as nonionic POPs, which are less likely to form chemical bonds with soil solids. Thus, chemisorption is unlikely to be a major rate-limiting factor governing the persistence and loss of hydrophobic organic chemicals in soils. Where a contaminant tends to ionize or contains polar functional groups (such as in the case of PFAS), then chemisorption may be important. In addition, biologically mediated degradation processes may alter the structure of nonionic organic chemicals so that they are more susceptible to chemisorption. In biologically-mediated degradation, the irreversible chemisorption of metabolites can also occur, and it may compete with biodegradation. It is important to understand fully the formation of the persistent residual fraction in soil, as it may determine whether the compounds remain chemically and, more importantly, biologically unavailable.

Sorption retarded intraparticle diffusion

Of the mass transfer mechanisms involved in the formation of persistent residual fractions it is generally agreed that sorption retarded intraparticle diffusion (SRPD) and sorption retarded intraorganic matter diffusion (SROMD) are the two primary rate-limiting factors. The SRPD has been defined as 'aqueous-phase diffusion of a solute within pores of microporous particles (e.g., sand grains) mediated by retardation resulting from instantaneous sorption to pore walls.' However, SRPD is often used as an umbrella term for several similar processes that occur by diffusion of organic compounds through pores. The above definition of SRPD refers to the molecular diffusion of chemicals in pore water that is retarded, chromatographic-like, by local sorption on pore walls. This process is more marked in larger mesopores (diameter $>2\ \mu\text{m}$), and the process may or may not be aided by sorption to and within organic matter lining these pores (see later for description of SROMD). As the diameter of a pore decreases, its tortuosity tends to increase, further hindering diffusion processes.

Fig. 2 illustrates graphically the various stages of diffusion that occur in exceptionally narrow pores (a few nanometers in diameter) traversed by a model PAH, benzo(a)pyrene. Compounds tend to enter these nanopores as they diffuse along gradually

Fig. 2 A conceptual diagram showing the mass-transfer limited processes leading to sorption-retarded pore diffusion. After Johnson D (2005) Pollutants/persistent organic (POPs). In: Hillel D (ed.) *Encyclopedia of Soils in the Environment*, pp. 264–271. Elsevier.

narrowing mesopores ($>2\ \mu\text{m}$) followed by micropores ($<2\ \mu\text{m}$) and eventually end up in nanopores whose diameter may be only a few nanometers in diameter (Fig. 2a). In extremely narrow pores, diffusion is often exceptionally slow due to the high viscosity of pore water. Polar minerals have one or more layers of water strongly sorbed on their surfaces. This ordered layering of molecules increases the viscosity of the water and greatly slows molecular diffusion within nanopores (Fig. 2b). The water contained in nanopores may be 'ice-like' and thereby greatly restrict solute diffusion. The tortuosity of pores becomes an increasingly important factor in the retardation of pore diffusion. In extremely narrow and tortuous pores, steric hindrance may further retard desorption (Fig. 2c). When this occurs, sorption is only very slowly reversible, contributing to the persistent residual fractions discussed earlier. Natural wetting-drying phases of a field soil will lead to expansion and contraction of clay mineral lattices (Fig. 2d), which can induce physical collapse of pores and physical entrapment of solute molecules within 'blind alleys' (Fig. 2e).

Fig. 2 therefore represents a series of steps that progressively restrict solute diffusion and retard desorption leading to persistent residual fractions of organic compounds in soils. These compounds, although chemically unaltered, are usually unavailable to traditional chemical extraction techniques and the assumption is that they are also not bioavailable. However, it is important to remember that, although such compounds are often referred to as irreversibly bound, this may not always be the case. Physical destruction of the soil aggregates they are associated with may release the compounds or at least increase their biological and chemical availability. Acidification dissolves the inorganic oxide cements that hold soil aggregates together and hence may similarly increase rates of pore diffusion and sorption.

Intraorganic matter diffusion

Intraorganic matter diffusion (IOMD) is the other important rate-limiting process involved in the desorption of persistent organic compounds from soils. Soil organic matter can exist as surface coatings, lining pores, or as discrete particles. Organic matter diffusion may be the primary rate-limiting process in soils with large organic matter contents but, since slow sorption also occurs in soils with little to no organic matter, it is clearly not the only rate-limiting sorption process. The IOMD is considered to be diffusion solely within the matrix of organic matter (OM), which is thought to resemble a polyelectrolyte polymer mesh, with retardation resulting from reversible sorption on the internal surfaces of organic matter. Organic matter polymers are said to have glassy (condensed, rigid) or rubbery (expanded, flexible) structures (Fig. 3). Diffusion in polymers occurs either by a place change mechanism, in which movement is accomplished by cooperative interchange of position in polymer segments and the penetrating molecule, or by a defect mechanism where the penetrant may jump between lattice defects, voids, and pores. The OM polymers consist of condensed, rigid 'glassy' phases through which diffusion is slow (Fig. 3b) or more expanded and flexible 'rubbery' structures (Xing and Pignatello, 1997) through which diffusion is faster (Fig. 3a).

In addition, some organic compounds may undergo 'Langmuir-like' adsorption (Fig. 3c) in internal voids in the OM matrix, which has been likened to a hole-filling mechanism (Xing and Pignatello, 1997). These slow diffusion processes lead to the formation of physically protected compounds which, as in the case of SRPD, are often mistakenly labelled as irreversibly bound residues. The OM diffusion and binding processes are in fact transitory since environmental variables may swell or soften

Fig. 3 A conceptual diagram describing the processes involved in sorption of organic chemicals in soil organic matter consisting of sorption on a rubbery phase (a), on a glassy phase (b), and through hole filling (c) mechanisms. Not to scale; Conceptualization based on Xing B and Pignatello JJ (1997) Dual-mode sorption of low-polarity compounds in glassy poly(vinyl chloride) and soil organic matter. *Environmental Science & Technology* **31**: 792–799.; Johnson D (2005) Pollutants/persistent organic (POPs). In: Hillel D (ed.), *Encyclopedia of Soils in the Environment*, pp. 264–271. Elsevier.

the OM matrix, converting it from a glassy to a more rubbery state and accelerating diffusion processes. Increasing temperatures, change in pH, and the presence of co-solvents can all act to increase the diffusivity of tightly bound compounds.

Recent work on new POPs (PFAS) has also shown that diffusion-related processes can make a significant contribution to their sorption on soil organic and mineral matter. For example, Xiang et al. (2018) in their studies on sorption of PFOA on various size fractions of soil particles observed that the pore sizes in their soils ranged from 8 nm to 16.9 nm in size (i.e., in the mesopore size range), thus allowing intraparticle diffusion of the linear structure of PFOA. They found that both the film and the intraparticle diffusion processes made a significant contribution to PFOA sorption on various size fractions of the soil. The role of intraparticle diffusion diminished as pore sizes became smaller. Intraparticle diffusion in the inner matrix of organic and mineral matter is expected to slow down their release and thus can potentially sequester the residues of organic compounds in the soil matrix.

In summary, it is probable that several mass transfer mechanisms are responsible for retarded diffusion leading to the formation of persistent residual fractions within most soils. Of these, the two most important are usually SROMD and SRPD. Although much work is needed to determine the exact contribution of each mechanism, it is likely that in most soils a synergy of both SROMD and SRPD is primarily responsible for the formation of persistent residual fractions. Residual fractions are often considered both biologically and chemically unavailable. However, as the preceding passages have shown, the mechanisms that lead to their formation are often transitory. This is particularly important when considering biological availability since the conditions that are known to enhance rates of diffusion often occur in the intestines of biological organisms (low pH, mechanical manipulation, and elevated temperatures). Hence, soil ingestion by an organism may have an impact upon a compound's availability and traditional extraction techniques used to determine the risk presented by a persistent residual fraction may be inaccurate.

Additional mechanisms involved in sorption of new POPs (PFAS)

The mechanisms elucidated in Figs. 2 and 3 above, are equally applicable to the sorption of several new POPs (pesticides and PBDEs flame retardants). However, for PFAS in soils several additional mechanisms are involved in their sorption and retention in soils, as discussed below.

The mechanisms of sorption or retention of PFAS in soils are more complex (Li et al., 2018) than conventional POPs (which are non-ionic and highly hydrophobic) because of their complex chemistry (e.g., amphiphilic and surfactant properties as well as surface activity) as shown in Fig. 4. The PFAS are composed of a hydrophobic C—F chain (tail) and a polar functional group (head). Therefore, their hydrophobicity increases with the length of the tail and consequently their sorption affinity to soil organic carbon (represented by the K_{oc} parameter,) also increases with increasing length of the C—F chain (Table 2b). While sorption or partitioning of some hydrophobic PFAS (long-chain compounds with >C8) on soil organic carbon may be similar to conventional POPs and may be the key controlling factor of their sorption behavior in soils. The sorption of the short-chain compounds is primarily driven by electrostatic interaction with the soil solid phase (Nguyen et al., 2020). For example, in the case of carboxylates or sulphonates the acidic head-group makes them anionic, which does not favor their sorption in net negatively charged soils. Only certain soils, such as those rich in Fe and Al oxides, could carry a net positive charge at an environmentally relevant pH range (4–9) and have the ability to sorb anionic POPs. It is noteworthy that several PFAS may exist as a cation or a zwitterion depending on the soil pH. While those containing amide and sulfonamido headgroups are cationic in nature, fluorotelomer sulfonamido alkylbetaines (FTABs) can form zwitterions in soils. In contrast to conventional POPs, the electrostatic interactions with the soil solid phase (both organic as well as mineral matter) play a major role in the sorption of PFAS in soils (Du et al., 2014; Li et al., 2018; Mejia-Avendaño et al., 2020).

Many PFAS, being surfactants, are surface-active compounds and tend to accumulate at the fluid-fluid interface (Fig. 4b). This has implications for the adsorption of PFAS in unsaturated soils with significant air:water interfacial area or those containing immiscible organic liquids i.e., non-aqueous phase liquid (NAPL) as co-contaminants (e.g., trichloroethylene). In such soils their adsorption at the fluid (air, NAPL)-water interface can be enhanced several fold compared to that in saturated soils (commonly used in the measurement of sorption coefficients on the soil solid phase). It has been noted that where sorption by the soil solid phase is small (e.g., sandy soils with low organic carbon) the contribution of interfacial adsorption towards PFAS retention in soils is higher. Brusseau (2018) observed that in unsaturated soils, air:water interfacial adsorption could contribute up to >80% of total retention in sandy soils (with low solid phase sorption) containing significant air-water interfacial areas, depending on the degree of saturation of soil pores with water. Several factors including solid phase sorption, soil texture, moisture content, PFAS concentration, co-contaminants and soil salinity influence the extent of interfacial adsorption of PFAS in soils.

Currently, the sorption behavior in soils of polyfluorinated PFAS with complex chemistry (e.g., FTAB zwitterions, fluorotelomer amines such as 6:2 FtSaAm, and other polyfluorinated precursor) is poorly understood, is more complex than expected and is difficult to predict by bulk soil properties (Barzen-Hanson et al., 2017).

The (Bio)availability and bioaccumulation of POPs in soils

The term 'bioavailability' is often discussed in the literature but rarely defined. In relation to the focus of this chapter, bioavailability refers to the extent to which humans and ecological receptors are exposed to POPs in soil. This is a broad definition and encompasses bioavailability to plants and microorganisms by a variety of potential routes. The amount of compound present in an organism will be a function of the rate of absorption versus the rate of excretion.

The POPs in soils are potentially bioavailable to many different organisms. In this chapter, a brief overview is provided of the bioavailability of POPs to those organisms that are thought to be most important. These are plants, bacteria and fungi, and grazing

(a) Reproduced with permission from Li Y, Oliver D and Kookana RS (2018) A critical analysis of published data to discern the role of soil and sediment properties in determining sorption of per and polyfluoroalkyl substances (PFAS). *Science of the Total Environment* **628–629**: 110–120.; (b) Reproduced with permission from Brusseau ML (2018) Assessing the potential contributions of additional retention processes to PFAS retardation in the subsurface. *Science of the Total Environment* **613–614**: 176–185.

animals. Macroinvertebrates, in particular earthworms, are dealt with in more depth as they may represent important routes for POPs to enter the food chain. Organisms such as earthworms that are in constant physical contact with the soil may accumulate considerably greater burdens of POPs in their bodies than the surrounding soil. These concentrations may not be great enough to cause either acute or chronic toxicity in the earthworms. However, many species feed on earthworms and will concentrate the lipophilic compounds in their body fat. The result is an increase in POP body burdens at a higher trophic level of the food chain. This phenomenon has become known as biomagnification and may lead to symptoms of toxicity in organisms that have little contact with soil POPs.

Despite being very different from hydrophobic POPs in terms of chemical properties, the bioaccumulation and biomagnification (through dietary uptake) of PFAS has been demonstrated in a wide range of organisms such as plants, invertebrates, fish and

humans (Houde et al., 2011; ITRC, 2020). While hydrophobic POPs have the tendency to migrate from water to the lipids of organisms, PFAS are proteinophilic (e.g., PFOS accumulate in serum albumin protein) and thus are somewhat unique among POPs. The PFAS (especially carboxylates and sulphonates) are predominantly found in protein-rich compartments (such as blood and liver) rather than in the fatty tissues. The conventional models, based on equilibrium octanol-water partition coefficients, cannot be applied to PFAS. In fact, the surface activity of ionic PFAS surfactants (being both hydrophobic and hydrophilic) prevents the empirical determination of K_{ow} . Nevertheless, the hydrophobic part of PFAS interacts with lipids and therefore the bioaccumulation of such compounds has been found to be related to their C—F chain length. The chemistry of PFAS head groups also affect their bioavailability and generally the PFAS with sulfonic acid headgroup are more bioaccumulative than carboxylic acid (Conder et al., 2008). The short chain PFAS (<7C-F chain) have low bioaccumulation and biomagnification potential.

Availability to plants

Uptake of POPs and other organic chemicals can occur through a number of pathways, such as passive and active uptake of the chemical by plant roots from soil solution, transport from the root to the shoot, transfer of the chemical from soil to soil air (depending on its volatility) and in turn uptake by plants through soil-air-plant pathway and particulate deposition to plant surfaces (Collins et al., 2006). In general, translocation of nonionic organic compounds (conventional POPs) from the roots to shoots is negligible because of low water solubility, high K_{ow} and strong associations of many compounds to soil particles and organic matter. Plant uptake of nonionic organic chemicals from soils is usually dominated by vegetative uptake of contaminated vapor from the surrounding air (McLachlan, 1996). Furthermore, many POPs are volatile in nature and may transfer into the gaseous phase from soil depending on the ambient conditions (temperature, humidity, etc.). Although large concentrations of soil-borne nonionic contaminants are rarely available for translocation by plant roots (due to their strong binding to soil particles), heavily contaminated soils can influence the concentrations of organic compounds in above-ground vegetation by the soil-air-plant route.

Perfluoroalkyl acids (PFCAs) being hydrophilic in nature are taken up by plants passively through water and therefore, their accumulation in plants is mainly controlled by rates of plant transpiration (influenced by plant species and environmental conditions). The bioavailability of PFAS in soil porewater will be regulated by their sorption affinity to soils, depending on PFAS chemistry (e.g., chain length, charge characteristics and hydrophobicity) as well as soil properties (organic carbon, clay content, pH and salinity). However, in a study on PFOS and PFOA uptake by seven different plant species it was observed that the PFAS concentrations in plant biomass were positively correlated with root protein content and negatively correlated with the root lipid content (Wen et al., 2016). This shows that because PFAS are proteinophilic, their uptake and translocation in plants could also be associated with protein regulation.

Availability to soil microflora

The 'availability' of organic compounds in soils to microorganisms is critical for their degradation and removal from the environment by either natural attenuation or bioremediation. Microbial biodegradation is a major process affecting the persistence of POPs in soils. The extent of POP bioavailability to bacteria in different soils may differ markedly, even under the same optimum growth conditions. Sorption has an important influence on the bioavailability of hydrophobic organic compounds in soils. A reduction in the rates of degradation with increasing soil sorption capacity has been noted for POPs due to their reduced bioavailability. Furthermore, a persistent residual fraction of POPs may remain unavailable to soil bacteria after remediation. This can be attributed to the slow migration of an increasingly large fraction of the POPs into the soil organic matter and mineral matrix with time.

As discussed earlier, POP chemical availability decreases with increasing residence time in soil (Alexander, 2000). This reduced chemical availability is often mirrored by an analogous decline in bioavailability. This 'ageing effect' may reduce the efficiency of bioremediation of a contaminated soil as a function of time. However, the reduced bioavailability may also reduce the potential toxicological threat of organic compounds in a soil. While a great deal of research on the bioavailability of POPs has been carried out for developing an accurate assessment of their bioavailability in soils, little is currently known about the bioavailability of PFAS. However, given PFOS and PFOA are anionic in nature, these are expected to be readily bioavailable to soil microflora. Nevertheless, these compounds and many other PFAS are extremely resistant to microbial degradation.

Availability to grazing animals

Soil ingestion by grazing farm animals can form a significant fraction of the total dry-matter intake, depending on the grazing habit of animal and forage conditions (e.g., plant species, sward height, etc.). While in some circumstances, soil formed up to 26% of the total diet ingested by sheep, generally the ingested soil forms <5% of the total diet (Duarte-Davidson and Jones, 1996; Weber et al., 2018; Collas et al., 2020). Free range chickens are more prone to POP contamination, as they take up more soil (per body weight) than other farm animals (Weber et al., 2018). For hens ingesting approximately 30 g soil per day, soils levels of 2–4 ng PCB-TEQ kg⁻¹ can exceed European Union standards (Weber et al., 2018). Thus, ingested soil may represent a potentially major route of uptake for soil-borne organic contaminants by farm animals. It follows that consumption of meat, eggs and or dairy products may be an important exposure pathway to humans (Weber et al., 2018). In the case of PFOS and PFOA, these compounds are more readily taken up by plants from soil solution and therefore the contamination of forage is likely to form a significant pathway in addition to soil ingestion.

Availability to earthworms

Earthworms can be extremely numerous, especially in pastureland where their biomass can be up to 272 g m⁻². Add to that the fact that an individual earthworm can consume up to 400 times its own weight in soil over a 12-month period, their importance in the dynamics and persistence of organic compounds in soils becomes evident. This high density and activity mean that up to 25% of the surface layers of soil may be turned over annually. A relatively large body lipid content means that earthworms accumulate POPs. Earthworms may facilitate faster release of certain sorbed residues, since a large quantity of soil passes through their guts and is consequently exposed to digestive enzymes that act on soil organic matter. Hence, the assumption that there is an analogous decline in chemical and biological availability of organic compounds may break down when an active (in this case gastrointestinal) uptake mechanism is involved as opposed to a more passive mechanism, such as contact between skin and soil.

Bioaccumulation of a wide range of PFAS (mostly PFCAs) in earthworms has been reported in the literature (e.g., Rich et al., 2015), generally increasing with the increasing chain length of PFCAs (7 to 12C—F). For equivalent chain length the bioaccumulation factors were found to be typically higher for sulphonic acids than for carboxylic acid analogues. Bioaccumulation of polyfluoroalkyl substances (e.g., 6:2 FTAB present in AFFFs), that upon transformation can form PFOA and PFOS, has also been found to related to their chain lengths (Munoz et al., 2020).

Concluding remarks

The family of POPs (under the Stockholm Convention) is growing. In addition to the original group of 12 chemicals, 16 new chemicals were added to the POP family in 2009. These included some with chemical properties similar to those of old POPs (e.g., flame retardants), but others such as PFAS had a unique and very different chemistry from that of the older POPs. Owing to their unique chemistry some of their environmental fate and transport processes and mechanisms resulting in their persistence, sorption, bioavailability and transport are very different from those of conventional POPs. Therefore, the conventional models, such as those based on their hydrophobicity and equilibrium octanol-water partition coefficients (K_{ow}), cannot be applied to PFAS. While new models and approaches are needed for PFAS, currently their fate and behavior in the soil environment remain poorly understood. A massive research effort is currently being directed internationally on developing better understanding of PFAS in the environment.

Abstract

This chapter introduces the issue of plastic pollution in agricultural soil. Plastic pollution occurs when diverse plastic materials such as pipes, plastic breeding tunnels or plastic mulch are fragmented into macroplastics (>5 mm) and microplastics (<5 mm), or when they are applied inadvertently with amendments such as composts or sewage sludge. The impacts of plastic particles on soil physical properties, plants, invertebrates and vertebrates are also discussed. The biotic and abiotic transport of micro and nanoplastics is explained briefly, and also their transfer into the food chain where their potential effects on various body systems of animals and humans, for example, those on human blood, have been documented.

Microplastics in agriculture

In recent years we have become more aware of several factors that promote soil contamination; we know that soil is a natural entity or body and it requires centuries to millennia to be formed. Therefore, as a non-renewable resource its functioning (i.e., nutrient cycles, water retention, infiltration) is affected by various agricultural practices, and strong measures need to be taken if we wish to restore soils or promote their re-establishment. We know that soil can be further eroded, thus making it infertile. In this chapter we will discuss the contamination by microplastics at agricultural sites.

What do we call plastic?

A common definition of plastic is a material that is at least partly made of an organic polymer and can be molded into solid, non-soluble, objects. For example, polyethylene is composed of a chain of carbon atoms whereas polylactic acid, a polymer used in biodegradable plastics, is composed of a chain of lactic acid (Fig. 1).

Most conventional plastics are petroleum-based, meaning that they are made from fossil resources such as natural gas, oil or coal. In Europe plastic production accounts for 4–6% of all the oil and gas used, and agricultural plastics represent about 4% of the plastic production in Europe. Plastics can also be produced from crops in which case they are called bio-based. For example, sugar cane (*Saccharum officinarum* L.) can be processed to produce ethylene, which can then be used to manufacture polyethylene. Plastics can be made of a single polymer or a blend of several types, assembled in different ways. The two main polymers used in agriculture are polyethylene (PE) and polypropylene (PP). Additives are used to adjust the elasticity, color, mechanical strength and degradability of the plastic. The chemical composition and manufacturing are tailored to fit the plastic's intended function.

Fig. 1 Chemical structure of common polymers used in agriculture: polyethylene (PE), polypropylene (PP) and polylactic acid (PLA).

Fig. 2 Estimated global annual quantities of agricultural plastics for different uses add up to 10.5 million tonnes. Plastic food packaging is not included and represents an additional 37 million tonnes. Data from Moine 2018, APE-Europe 2021, FAO (2021) Assessment of Agricultural Plastics and Their Sustainability—A Call for Action. Rome, Italy.

Plastic use in agriculture

In agriculture, plastics are mostly used in the form of film as it constitutes a light, resistant, elastic, cheap and waterproof barrier (Fig. 2, FAO, 2021). Plastic mulch, greenhouse cover and bale wrapping (Fig. 3) are the three main agricultural practices that use plastic films. Plastics also provide other services: crop protective nets; irrigation pipes; ropes and twines; crates and containers for farming products; controlled-release coatings. Some of these plastics are placed directly in contact with the soil. This is the case for mulches, irrigation pipes and controlled-release coatings. We will focus on plastic mulches as they are an example of a wide application of plastic that is in direct contact with the soil.

Plastic mulches in agriculture

An estimated 2.5 million tonnes of plastic mulch are used annually worldwide, covering about 140,000 km² (twice the size of the Netherlands and Belgium together, FAO, 2021). Plastic mulch is used for one or all of the three following reasons:

Fig. 3 Bale wrapping with nets and twines (A.), with silage film (B.) and the main polymers used, HDPE, PP and LDPE. Adapted from FAO (2021) Assessment of Agricultural Plastics and Their Sustainability—A Call for Action. Rome, Italy.

Fig. 4 Fields covered with low density polyethylene (LDPE) plastic mulch before the harvest of parsnip (Panel A) and after the harvest of Kohlrabi (*Brassica oleracea*, var. *gongylodes*, Panel B) in Southeast Spain.

- *Increasing soil temperature*: Plastic mulch was first noted for its ability to increase soil temperature in the 1950s. Higher soil temperatures increase nutrient availability, enhance nutrient uptake by roots, increase the number and activity of soil microorganisms, speed up plant germination and growth, and can help to control pathogens, e.g., *Tuta absoluta* in tomato (*Lycopersicon esculentum* Mill.) plants leading to higher and earlier yields. Therefore, plastic mulch may reduce the need for fertilization (for appropriate references for this section please see Further reading).
- *Increasing water use efficiency*: Water use efficiency is estimated by dividing the yield per hectare by the total amount of water applied. Plastic mulch is a barrier that prevents water evaporation from the soil and therefore increases water availability for plants. Plastic mulch can also increase rainwater harvesting when associated with ridge–furrow tillage; the ridges being mulched by plastic and plants growing in the furrows. An analysis of 266 studies in China, showed that plastic mulching significantly increased crop yield by 24% and water use efficiency by 28% on average (Gao et al., 2019).
- *Decreasing weed growth*: Opaque (often black) plastic mulch limits weed growth by preventing the light from reaching the soil. Plastic mulch can reduce weed emergence by 64–98% during the growing season, depending on the surface covered with plastic. In this sense plastic mulch can contribute to reducing the use of herbicides. Nevertheless, with a clear or transparent plastic mulch, the application of a pre-emergent herbicide is needed.

Because of these benefits, plastic mulch is used under various climatic conditions, in open fields and in greenhouses for the production of different crops, and under both organic and conventional farming practices. Plastic mulch is often partially buried in the soil to prevent it from being blown away by the wind (Fig. 4).

In summary, we showed that plastics are very diverse and provide many benefits to farmers. Intensive agriculture has great potential to feed the world population, however, this success is not without drawbacks.

Plastic, from ubiquitous use to ubiquitous contaminants in agricultural soil

The general public and the scientific community first became aware of the issue of plastic debris by observing their accumulation in the oceans after Captain Moore in 1997, since then, land has been identified as a major source and reservoir of plastic debris. Plastic debris is formed through the fragmentation of plastics in the environment. Plastic degradation relies on two main processes: weathering and biodegradation.

Weathering refers to abiotic reactions such as thermal degradation, photo-degradation, oxidation, hydrolysis and to mechanical degradation (e.g., wind or plowing). Weathering plays an important role in the degradation processes, as weathered plastic will undergo faster biodegradation. For example, photo-degradation can change the chemical structure of plastic polymers making them easier to degrade for microorganisms (Napper and Thompson, 2019).

Biodegradation of a polymer is a biological process leading to its complete or partial conversion to water, CO₂ (carbon, dioxide), CH₄ (methane) and new biomass by microorganisms (mostly bacteria and fungi). The biodegradation process can be divided in three different steps (Sander, 2019):

1. The organisms colonize the polymer and grow on its surface (Fig. 5).
2. The organisms degrade the polymer. They do this mostly by secreting enzymes (e.g., hydrolases) that can depolymerize the polymer. Depolymerization is the breaking of chemical bonds in the polymer that leads to smaller molecules. The main process of depolymerization is catalyzed hydrolysis with enzymes.
3. Finally, the hydrolysis products released from the polymer are used as an energy source or a carbon source for the microorganisms leading, for example, to the emission of CO₂ or the increase of biomass.

Fig. 5 Scanning electron microscopy images of the surfaces of polybutylene adipate-co-terephthalate (PBAT) films that were incubated with an agricultural soil in the laboratory (6 weeks; temperature of 25 °C). The images illustrate colonization of PBAT films by both fungi and unicellular organisms. Panel B shows a magnification of the area highlighted in panel A. Adapted from Sander M (2019) Biodegradation of polymeric mulch films in agricultural soils: Concepts, knowledge gaps, and future research directions, *Environmental Science and Technology*, 53: 2304–2315.

Fig. 6 Examples of the categorization of plastic debris according to size as defined in scientific literature. Adapted from Hartmann NB, T Hüffer, RC Thompson, M Hassellöv, A Verschoor, AE Daugaard, S Rist, T Karlsson, N Brennholt, M Cole, MP Herrling, MC Hess, NP Ivleva, AL Lusher and M Wagner (2019) Are we speaking the same language? Recommendations for a definition and categorization framework for plastic debris. *Environmental Science & Technology*, 53(3): 1039–1047.

The degradation of plastic produces smaller and smaller debris. Debris size is frequently classified into three categories: nanoplastics < microplastics < macroplastics (Hartmann et al., 2019). However, the size of plastic debris is, in fact, a continuous variable and no defined boundaries exist for these categories (Fig. 6). Most often the boundary between microplastics and macroplastics will be based on the method of identification used, and so varies from one study to the other from 500 µm to 5 mm.

Plastic debris can also be classified on their origin. As plastics have many functions, plastic debris have many different origins. For agricultural sources we can distinguish direct sources: the plastic is used for the beneficial action it is expected to offer; and indirect sources: the plastic is transported to the field without expecting a benefit from it. In addition, when debris is small, it is interesting to know if it was manufactured like this or has been degraded. Therefore, we distinguish primary microplastic from secondary microplastic which are particles derived from the fragmentation of bigger debris. Secondary microplastics have gone through degradation, which has modified their size, shape, physical and or chemical properties.

Examples of direct sources of plastic in agriculture are plastic mulch, irrigation pipes and plastic coatings (Table 1). The degradation of plastic mulch and irrigation pipes into smaller debris is a direct source of secondary microplastics (Fig. 7), whereas fertilizers coated in plastic are a direct source of primary microplastics. Organic fertilizers such as sewage sludge (Corradini et al., 2019) and compost are examples of indirect sources of microplastics. However, sewage sludge can contain primary microplastics from cosmetics and compost can contain secondary microplastics from the fragmentation of a wrongly sorted plastic item. When

Table 1 Examples of direct and indirect sources of primary and secondary microplastics in agriculture.

		Degradation stage of the plastic	
		Primary microplastics	Secondary microplastics
Origin of the plastic	Direct source	Microplastic coating for slow release fertilizers	Degradation of agricultural plastics in the soil, such as twines, plastic mulch, irrigation pipes
	Indirect source	Microplastic from personal care products in sewage sludge	Tire fragment in sewage sludge, wrongly sorted plastic packaging in compost, oversight contamination

Fig. 7 Light density polyethylene plastic mulch after harvest of Kohlrabi in Southeast Spain. The plastic mulch covers an irrigation pipe to improve the water use efficiency (Panel A). The sides of the mulch film are buried into the soil making complete removal impossible and leading to debris accumulation (Panel B).

they are applied to the field for fertilization, contaminated sewage sludge and compost bring with them microplastics that are of no use to the farmers.

The occurrence of plastic in agricultural soils has been described in many studies, with a range from 0 particles kg^{-1} to 50,000 particles kg^{-1} (e.g., van den Berg et al., 2020). For example, it has been found in soils after plastic mulching (Meng, 2021), and compost (van Schothorst et al., 2021) and sewage sludge applications (van den Berg et al., 2020). In China, the extensive use of low density polyethylene (LDPE) plastic mulch is leading to worrying levels of residues (Liu et al., 2014). Detrimental effects of plastic residues have been observed when the contents in soil exceed 270 kg ha^{-1} (Gao et al., 2019). Estimated a 3% decrease in crop yield for every additional 100 kg ha^{-1} of film residue in soil.

The LDPE is the most used polymer for plastic mulches; it has to be removed from the fields after harvest and incomplete removal leads to plastic debris accumulation (for appropriate reference please see Further reading). Some plastic producers have tried to improve the degradation processes of plastic mulch by adding pro-oxidant additives to LDPE to avoid the need for plastic mulch removal and thus, the accumulation of plastic debris. With these aims in mind, pro-oxidant additive containing (PAC) plastic, also called "oxo-degradable" or "oxo-biodegradable," was developed but it has proved to degrade poorly in soils (Hogg et al., 2016) leading to it being banned in June 2019 by the European Parliament. Another attempt to solve the problem of plastic debris accumulation from mulch has resulted in the production of biodegradable (BIO) plastic polymers. Biodegradable mulch can be made from a diversity of biobased or petroleum-based polymers or a blend of both (Sintim et al., 2020). Biodegradable mulches are expected to degrade into water, CO_2 , methane, energy and new biomass in soil with the help of microorganisms. These mulches were designed so that they would degrade by 90% after 2 years in the soil (Standard ISO 16929). However, research has found that biodegradable plastic mulch does not degrade as fast as expected under some field conditions, and leaves residues in the soil after more than 2 years (Sintim et al., 2020). In addition to its potential incomplete degradation, BIO plastic mulch also presents a threat to plant growth. Two studies have found a reduction in the production of wheat (Qi et al., 2018) and common beans (Meng, 2021) in the presence of 2% (w/w) of BIO residues added to the soil. Processes leading to the decrease in crop production are not well understood yet and need more investigation.

One explanation for the decrease in crop production could be the reduction of beneficial microorganisms or the increase of plant pathogens in the presence of BIO plastics. Plastic debris can affect the soil microbiome, and BIO plastics have a stronger potential to do so because they are degraded by microorganisms (Sander, 2019). Plastic debris could be habitats for microorganisms, with the

formation of a biofilm, for example, (Amaral-Zettler et al., 2020). In addition, plastics could be a source of nutrients, mostly carbon. Several organisms have been reported to degrade plastic, even LDPE. Finally, plastic could release chemicals that are toxic for some microorganisms. As explained previously, we have barely any information about the chemicals present in commercial plastic and they could be released due to plastic degradation in the soil. We know that some additives can directly affect the soil microbiome (for appropriate reference please see Further reading).

Plastics and their additives can affect other organisms. Study of the exposure of soil animals to microplastics showed that many organisms do ingest plastics. However, ecotoxicological effects at environmental concentrations are still uncertain (Ng et al., 2018). Microplastics ingested by organisms can travel into the food chain. For example, microplastic concentrations increased from soil (0.87 ± 1.9 particles g^{-1}), to earthworm casts (14.8 ± 28.8 particles g^{-1}), to chicken feces (129.8 ± 82.3 particles g^{-1}) in home gardens in southeast Mexico (Huerta Lwanga et al., 2017). An increase in earthworm mortality has been recorded when exposed to 28%, 45%, and 60% of microplastics in litter (Huerta Lwanga et al., 2016), but these plastic contents are higher than average environmental contents. Moreover, nanoplastics decreased the growth, locomotor activity, and intestinal microbiota viability of snails that were feeding on plants grown in soil with 10 mg kg^{-1} and 100 mg kg^{-1} nanoplastics added (Chae and An, 2020). The effects of plastics on terrestrial organisms can also be caused by additives and other contaminants that may leak from the plastic debris (for appropriate reference please see Further reading). Many plastic additives are suspected of being endocrine disruptors. This means that they may interfere with animal hormones and therefore impact the entire organism (for appropriate reference please see Further reading). Plastic debris is also ingested by larger organisms resulting in various negative effects. These effects include blockage of the intestinal tract, inhibition of gastric enzyme secretion, reduced feeding stimuli, decreased steroid hormone levels, delays in ovulation and even failure to reproduce. Though it is still difficult to draw definitive conclusions from the literature, early studies about plastics in soil concur with the wider base of aquatic plastic toxicology in the sense that plastics are a threat to soil biota (Helmberger et al., 2020). Toxicity of aquatic plastic debris has been better described and marine animals like sea turtles illustrate well the problem of plastic contamination in the environment. Water and wind transport link land and aquatic plastic contamination, making plastic debris a ubiquitous contaminant.

Uncertainties shrouding plastic content assessment in soil

Microplastic residues are more or less everywhere, but they are not easy to spot. However, it is not necessarily their size but their diversity which makes them difficult to detect. We cannot over emphasize that plastics are diverse and complex contaminants. Commercial plastics can be composed of a blend of different polymers and contain several additives. Plastic additives have been proved to be toxic, possibly even more toxic than the main polymer (for appropriate reference please see Further reading). The detection of plastic additives would rely on targeted screening of likely chemicals, which occurs for pesticides for example. However, additives are the secret ingredients used by industries making targeted screening difficult. If we leave out additives for simplicity, we can apply various techniques to assess plastic contamination. For plastic polymers we can measure the number of particles, contact surface, mass of debris, type of polymer and their degradation over time.

The extraction method of Zhang et al. (2018) was developed for LDPE and consisted of a stereomicroscope visual selection (SMVS). The microplastics are identified visually based on their shape, color, brightness, and response to heat. The SMVS method has the advantage of being relatively fast and cheap, but relies on observer judgment and attention which can vary with different users. Spectral methods (e.g., Raman or Fourier transform infrared) are used to identify several types of plastic by comparing the spectra of the plastics analyzed with a spectral library. Spectral methods provide a 2-D image of the sample with number, surface area and best polymer type matched in the library for each particle (Corradini et al., 2021). Other methods do not directly report the size or number of particles but analyze the mass of all plastic present in the sample. This is the case for thermal extraction desorption gas chromatography mass spectrometry (TED GC-MS) (for appropriate reference please see Further reading) and pyrolysis–gas chromatography–mass spectrometry (Py-GC-MS). Essentially, plastic particles are burned and the molecules emitted are analyzed by gas chromatography. It is a sensitive and well-established method for the characterization and mass-quantification of many polymer types and their organic additives (for appropriate references of this section see Further reading).

Each method relies on a different property of the plastic and therefore is likely to underestimate the total plastic content. In addition, each method is suitable for a certain particle size. For example, with SMVS, smaller particles are more difficult to identify than larger ones simply because they are more difficult to detect. It is another factor suggesting underestimation of the total plastic number. In general, the smaller the plastic becomes the more difficult it is to analyze. The identification of nanoplastics remains a challenge and new methods have to be validated in environmental samples. Raman spectroscopy and pyrolysis–gas chromatography/mass spectrometry (py-GC-MS) are the most promising methods. In addition, sample pre-processing and the method of plastic extraction are also major factors for microplastic analysis. To summarize, the diversity of plastics, of matrices (e.g., soils, composts, feces) and of variables (number, area, mass, polymer type) mean that there is no single method able to answer all questions (for appropriate references of this section see Further reading).

A combination of different methods could provide a better description of environmental microplastic samples. For example, to compare the quantity of plastic left after spiking known amounts of plastic in soil, the best option could be to use a thermal desorption method to estimate the mass balance and to combine it with the SMVS method to investigate evolution of the plastic size distribution. Spectral methods will be less relevant in this case since the type of polymer applied would already be known. On the other hand, a spectral method is recommended to identify the type of plastic in field assessments. In summary, we

recommend adapting the method of assessment to the specific interest of the study. For example, to estimate the probability of particle ingestion the amount of debris will be most important (Helmberger et al., 2020); for the formation of biofilms, the total area will be the dominant factor (Sander, 2019); and for input/output balances the mass is generally favored. Moreover, many processes will be influenced by the size of the debris. For example, a study on plastic ingestion may focus on millimeter-size debris for mammals, micrometer-size for earthworms (Helmberger et al., 2020) and nanometer-size for plant roots (Chae and An, 2020). Now that we have a better idea of what we are measuring, what are the expected consequences for environmentally relevant plastic contents?

Effects of plastic residues on the environment

Effect on soil physicochemical properties

Various studies have tested the effects of plastic debris on soil physical properties. Qi et al., 2020 tested macro- and micro-plastic particles from the addition of LDPE and BIO mulches (0.5%, 1% and 2% *w/w*) to a sandy soil. They reported a decrease in field capacity with LDPE debris and an increase with BIO debris suggesting a strong effect of the type of plastic on water retention. No effects were observed for the soil pH, electrical conductivity and aggregate stability. Under various conditions de Souza Machado et al. (2019) observed a reduction of aggregate stability in the presence of polyamide beads (diameter of 15–20 μm) and polyester fibers (~5000 μm in length and ~8 μm in diameter). In another study they also showed that polyester and polyacrylic fibers reduced aggregate stability. They suggested that the fiber shape, as an elastic and linear particle creates tension inside the aggregates (Fig. 8). Apart from confirming the effect of plastic on soil properties, these findings highlight the fact that different results can be expected from different plastic particle polymers, shapes and sizes. In addition, most studies emphasize that aging of the plastic in the soil will possibly modify the interaction with soil particles; and soil properties (i.e., soil density, infiltration, water holding capacity De Souza Machado et al., 2019), are closely related with soil type and texture (Yang et al., 2020). Therefore, further research is needed to focus on different soil types, plastic shapes and types.

Effect on the soil microbiome

Meng et al. (2023) and Qi et al. (2020) observed a modified soil bacterial community after the introduction of plastic mulch debris. There are different hypotheses that could explain the effect. First, the plastic may alter the soil physical properties, which could then modify the soil microbiome. For example, if biodegradable plastic could increase the soil water retention as reported in Qi et al. (2020), organisms adapted to higher water content would thrive. Another hypothesis is that plastic could serve as a habitat for certain microorganisms, with the formation of a biofilm (Amaral-Zettler et al., 2020). In addition, plastics could be a source of nutrients, mostly carbon. Several organisms have been reported to degrade plastic even LDPE. Finally, plastic could release chemicals that are toxic for some microorganisms. As mentioned above, we have little information about the chemicals present in the commercial plastics that could be released with plastic degradation in the soil. It is known that some plastic additives can directly affect the soil microbiome (for appropriate reference see Further reading).

Effect on plants

Qi et al. (2018) and Meng (2021) also observed a significant effect of BIO plastic but not of LDPE on wheat (*Triticum aestivum* L.) and common bean (*Phaseolus vulgaris* L.), respectively. The impact of BIO could come from effects discussed earlier such as change in

Fig. 8 Polyester fibers (A) and polyacrylic fibers (B) incorporated into soil aggregates. The white bar in each panel represents 1 mm size. Adapted from de Souza Machado AA, CW Lau, J Till, W Kloas, A Lehmann, R Becker and MC Rillig (2018) Impacts of microplastics on the soil biophysical environment. *Environmental Science & Technology* 52(17): 9656–9665.

Fig. 9 Effects of microplastics on plants. Taken from Rillig MC, Lehmann A, de Souza Machado AA, & Yang G (2019) Microplastic effects on plants. *New Phytologist*, 223(3): 1066–1070.

the soil physical properties or in the microbiome (Meng et al., 2023). There is uncertainty about whether beneficial or pathogenic organisms might be suppressed or enhanced by the BIO plastic. Another theory could be nutrient competition between the organisms degrading the BIO plastic and the plant. For instance, Meng (2021) reported less nitrate but more organic nitrogen in soils with 2% BIO plastic. This effect would depend on the fertilization applied and degradation of the plastic. More research is required for greater understanding. Moreover, a direct effect of plastics on the plant should be considered. Rillig et al., 2019 (Fig. 9) describe effects on soil conditions that consequently affect plants (i.e., soil microbial community, root traits). Bosker et al. (2019) reported that nanoplastics blocked the pores of cress (*Lepidium sativum* L.) seed capsules and reduced the rate of germination. Nanoplastics could also potentially enter the roots leading to oxidative stress in the plant (Giorgetti et al., 2020). As they are more easily degraded it is likely that BIO plastics generate more nanoplastics, which explains why they have more impact on plant growth. Finally, chemicals leaked from the BIO plastic also have unknown consequences for the plant. All these hypotheses remain unverified and could be combined to explain detrimental effects of plastic residues on the plant. If plastic ends up in plants we need to consider the consequences of plastic further up the food chain.

Effect on soil invertebrates and vertebrates

Recent studies have clearly indicated how microplastics produce changes in soil macroinvertebrates. Earthworms, for example, ingest microplastics (Huerta Lwanga et al., 2016), and carry them in and on their bodies (Huerta Lwanga et al., 2016; Rillig et al., 2017). The effects observed are weight loss, oxidative stress (Rodríguez-Seijo et al., 2018), histological damage (Rodríguez-Seijo et al., 2018) and mortality (Huerta Lwanga et al., 2016).

Larger concentrations of microplastics were found inside earthworm biogenic structures compared to the bulk soil. They also transport microplastics into the deeper soil layers (Rillig et al., 2017; Huerta Lwanga et al., 2022). In addition, other invertebrates such as snails, springtails, and mites are also affected by the presence of microplastics; they carry the microplastics inside them (Song et al., 2019) and displace them, and the predator–prey relationship in mites is affected. When this contaminant is present, macro and meso invertebrates are also affected, and there is a response or adaptation that we need to understand better about which processes are involved in these adaptations.

Vertebrates such as sheep, vultures and chicken are vulnerable to microplastics through their ingestion (Beriot et al., 2021; Borges-Ramírez et al., 2021; Huerta Lwanga et al., 2017). There are few studies that have reported how such animals, which also interact with agricultural systems (sheep), ingest the plastic mulch products if they are not removed, and then carry them in their bodies to nearby sites.

Effect on soil ecosystem services

When earthworms or macroinvertebrates lose weight, or are less active in decomposing organic matter, promoting infiltration or aggregation (Rillig et al., 2019, de Souza Machado et al., 2019, fig. 9) there are adverse effects on ecosystem services in terms of change and degradation. The incorporation of organic matter from the soil surface to the deeper soil layers is also altered, as the earthworms transport microplastics from the soil surface to the soil matrix, which contaminate the tunnels and burrows they build. The nutrient cycle and water retention are also affected when microplastics are introduced by earthworms (Huerta Lwanga et al., 2022). Moreover, the number and sizes of burrows are also modified when plastic particles are on the soil surface (for appropriate reference see Further reading). More research is necessary to understand this process better at the level of the earthworm burrows or galleries, together with the microplastics and the microorganisms that inhabit them.

Less germination of *Lolium perenne* L. has been noticed together with weak soil aggregate stability when LDPE microplastics were present in soils, PLA also decreased earthworm biomass in combined systems with this plant (for appropriate references see Further reading).

Transport of microplastics

The transport of microplastics is not well described in many of the existing studies, nevertheless it is very probable that microplastics are everywhere; there are not pristine areas without microplastics. They have been found in remote areas such as in the Swiss Alps or the Arctic (for appropriate reference please see Further reading), even in those places where there are no clear traces of human activities.

The transport of microplastics in terrestrial environments is carried out by abiotic and biotic factors (Huerta Lwanga et al., 2022); among the most important abiotic factors are air and water. Once microplastics are present on the soil surface they are moved by the wind (soil erosion), or run off by the water, leached or moved beyond.

Abiotic transport

The transport of microplastics is size dependent; it is estimated that small particles such as micro or nanoplastics are highly transportable compared to macroplastics. In agricultural areas, once the soil is polluted with microplastics they will move from the soil surface into deeper layers according to the type of soil matrix and follow preferential flow paths (Yu et al., 2019; Huerta Lwanga et al., 2022). There is a need to understand how the processes are taking place, and which types of plastics, soils, and sizes are involved in microplastic transport (Huerta Lwanga et al., 2022). Transport of microplastics to the ground water has already been reported. Polyethylene, polyester, and polyvinylchloride microplastics (50–150 µm) have been found in ground water, and in drinking water, representing a potential health risk (for appropriate reference please see Further reading). Wind transport of microplastics has been reported (Rezaei et al., 2019); this involves the fibers which are more susceptible to this type of transport.

Biotic transport

Among biotic factors, microplastics are being transported through the biogenic structures of invertebrates and vertebrates in the soil (feces), through the tunnels or burrows in the case of earthworms and through the bodies of invertebrates or vertebrates. Microplastics are even taken as “food” in the case of springtails (Maaß et al., 2017), or snails (Song et al., 2019).

Once the invertebrates in soil are in contact with microplastics, depending on the concentrations and time of exposure, they become impregnated with the particles and electrostatically transport them horizontally or vertically (Fig. 10). Earthworms ingest microplastics together with leaf litter and transport them from the soil surface to the lower soil layers, in particular those earthworms that form vertical tunnels, (i.e., the microplastics in hotspots, Huerta Lwanga et al., 2022, Rillig et al., 2017).

The situation is similar for terrestrial vertebrates such as chickens (Huerta Lwanga et al., 2017), sheep (Beriot et al., 2021), and vultures (Borges-Ramírez et al., 2021), which, once they have ingested the plastics, carry them in their bodies until they are defecated or regurgitated.

It becomes more complicated when the plastic particles are combined with other substances such as pesticides, metals or the same additives that are added to plastics to make them more flexible or resistant, then the microplastics carry other pollutants (Huerta Lwanga et al., 2022). Nevertheless, this brief chapter cannot discuss the interactions that take place between plastic particles and other pollutants. During transport, the interaction between plastics and pollutants such as pesticides play a significant role. For example, pesticides can be adsorbed or not according to the type of pesticide and the type of plastic, a situation that might occur at industrial agricultural sites due to the use of plastics, agrochemicals and pesticides. More research is required to understand these phenomena.

Fig. 10 Microplastic (MP) transport by soil invertebrates. Taken from Helmberger MS, Tiemann LK, & Grieshop MJ (2020) Towards an ecology of soil microplastics. *Functional Ecology*, 34(3): 550–560 and modified by Huerta Lwanga EH, Beriot N, Corradini F, Silva V, Yang X, Baartman J, . . . & Geissen V (2022) Review of microplastic sources, transport pathways and correlations with other soil stressors: A journey from agricultural sites into the environment. *Chemical and Biological Technologies in Agriculture*, 9(1): 1–20.

Microplastics and humans

It has recently been reported that humans contain microplastics in their feces, and Leslie et al., 2022 reported $1.6 \mu\text{g mL}^{-1}$ of plastic particles in human blood. The main plastic residues were polyethylene terephthalate, polyethylene and polymers of styrene. The implications for humans being exposed to different types of plastics, and also to different pesticides is yet to be explored. The toxicity of plastic particles to soil invertebrates (weight loss, and mortality depending on concentrations and time of exposure) is known, but not in humans. Prata et al., 2020, described how exposure of humans to microplastics by ingestion, dermal contact, and respiration (Fig. 11) can affect various human systems (parasympathetic, and sympathetic). Genotoxic and cytotoxic effects of plastic particles in blood cells were explored by Çobanoğlu et al. (2021); the authors concluded that microplastics can generate genetic instability in blood cells, but they did not observe a clear cytotoxic effect on the studied lymphocytes, and recommend more

Fig. 11 Microplastics effects on humans. After Prata JC, da Costa JP, Lopes I, Duarte AC, & Rocha-Santos T (2020) Environmental exposure to microplastics: An overview on possible human health effects. *Science of the Total Environment*, 702: 134455.

research. It is already reported that microplastic fibers have been detected already in lung biopsies, and the authors consider that injury or death is expected if people are chronically exposed to airborne microplastics (for appropriate reference please see Further reading). The sources of airborne microplastics are different: among them are fibers from synthetic clothes, erosion and synthetic rubber tires. Further research is required to understand the effects of microplastics on humans, under different conditions, and when other stressors are also present as pesticides or heavy metals.

Concluding comments

Microplastics are particles smaller than 5 mm, and are emergent pollutants. They are present in most agricultural soils tested. They have mainly entered agricultural systems due to the fragmentation of plastic materials used in agriculture (e.g., plastic mulches, greenhouses, twines), the application of inputs to the soil (e.g., plastic coated fertilizers, sludge, compost) or through external contamination (e.g., atmospheric deposition, dumping). Microplastics are transported by biotic and abiotic factors, disseminated along the food chain, and result in strong potential environmental and human risks.

To summarize, much still remains to be studied and understood with respect to microplastics. They are not static or isolated, and also carry other pollutants, and consequently various interactions take place in the soil, with or without the organisms that inhabit it. We invite the reader to go deeper into the subject by consulting some sites of interest like those included in European projects such as the H2020 projects MINAGRIS (www.minagris.eu) and PAPILLONS (www.papillons-h2020.eu).

Acknowledgments

Research is a team work, therefore we thank all those who have done research with us and NWO women in STEM (19342), and also we thank all investigations related with microplastics in this area, because every day we understand more how microplastics interact with the environment, and so we expect in the near future to find solutions for mitigating this pollution.

We also thank you “the readers of this chapter,” because we firmly believe that more heads think better than one (Mexican proverb), and much better when those heads are informed, please share this information with your students and colleagues.

Abstract

Global population expansion generates large volumes of diverse waste. As a subset of global waste, municipal solid waste (MSW) includes household, business, institutional, and construction waste that may be processed, composted, recycled, and or disposed of at managed sites. Modern sustainable development is predicated on transitioning from linear (take–make–dispose) to circular (take–make–reuse) waste economies; however, underlying all waste management, is a concern for human, and aquatic-, and terrestrial- ecosystem health. In response, this chapter describes various waste management strategies in Western societies, including recycling, composting, energy recovery, treatment and disposal. Moreover, the potential impact of each strategy on soils is emphasized.

Key points

- Municipal Solid Waste (MSW) involves diverse waste products, including non-hazardous recyclables, compostables, in addition to household, business, institutional, and construction waste.
- MSW can sorted into streams as compost, recyclable material, biosolids (as a product of wastewater treatment), energy recovery streams (thermal and non-thermal waste-to-energy, pyrolysis, gasification, landfill gas utilization), and should no further resource be able to be extracted, all other wastes are landfilled.
- When successful, engineered solutions can reduce the volume of waste, improve resource recovery, and limit the potential toxicity to soils, and the broader terrestrial and aquatic environment.
- Despite decades of waste reduction education globally, the waste generated per capita continues to increase unsustainably.
- Potential pathways of soils and water contamination include, but are not limited to: (i) landfill leachate (precipitation over landfill products, which may mobilize contaminants into soil, groundwater, and surface waters); (ii) gas production from landfills and waste incineration; (iii) non-compostable wastes and environmentally-deleterious compounds, which may be present in biosolids or composts, being incorporated into soils through land-application.

Introduction to municipal solid waste (MSW)

Definition of municipal solid waste (MSW)

In North America, municipal solid waste (MSW) refers to any non-hazardous or hazardous items that consumers have no further use for and throw away. Municipal solid waste is diverse, including recyclables and compostable materials, as well as waste from households, businesses, institutions, and construction and demolition sites. Once collected, MSW is recycled, processed, or disposed of at managed sites. Similarly, the European Commission defines MSW as “waste from households, as well as other waste which, because of its nature or composition, is similar to waste from households” (European Commission (EUC), 1999).

Following a linear consumption model (i.e., take–make–dispose), Western societies have, for centuries, metabolized raw materials into the food, water, air, and shelter needed to sustain human life, repetitiously creating municipal solid waste (and waste generally) as a by-product.

Municipal solid waste (MSW) is waste predominantly generated by urban populations and collected for disposal by municipal authorities (Tchobanoglous and Kreith, 2002). In Canada, MSW includes waste generated from residential and industrial, commercial, and institutional (ICI) sources. The ICI sources can include wastes from office buildings, shopping malls, schools or hospitals. The MSW can also include (i) organic (putrescible) wastes, which are biodegradable and compostable, such as food scraps, lawn and garden waste, used paper products and cardboard; (ii) recyclable waste such as plastics, metals, paper, and cardboard; (iii) construction, renovation, and demolition (CRD) waste such as wood (clean, engineered, treated, and painted), asphalt roofing and drywall; in addition to (iv) residual materials that comprise wastes that cannot be recycled or composted.

Municipal solid waste differs from liquid waste that is collected through sewage and sanitary networks to be processed subsequently in wastewater treatment plants (WWTP). However, MSW and liquid waste overlap in the creation of processed sewage sludge (i.e., biosolids) that is then managed as solid waste and either (i) land-applied, (ii) disposed of in landfills, or (iii) incinerated (Puddephatt et al., 2022).

Waste production and management are regulated in many countries, albeit differently by jurisdiction. Nevertheless, waste management regulations globally were enacted to preserve human health, and minimize the potential contamination of aquatic resources (e.g., potable water, fisheries) and terrestrial ecosystems (by physical littering; landfill leachate). In addition, regulations govern the generation of gases during waste decomposition (including methane, carbon dioxide, carbon monoxide, hydrogen sulfides, etc.) (see Manning, 2005, for review).

History of municipal solid wastes (MSW)

In North America, historically, waste from residential, industrial, commercial, and institutional sources was collected and dumped into rivers, oceans, and unlined landfills, as land and water were viewed as an inexhaustible ‘sink’ for waste. However, as the unsustainability of such practices became very clear, and by the 1960s, citizens and lawmakers mobilized, and Congress passed the Solid Waste Disposal Act (SWDA) of 1965. This framework was the beginning for better waste control from all sources. Concomitantly, with the formation of the United States Protection Agency (USEPA) in 1970, federal lawmakers worked with the states to pass the Resource Conservation and Recovery Act (RCRA) of 1976. A transformation of the waste industry has been steadily making progress over the past half century, with RCRA national waste disposal goals that include (i) protecting human health and the environment from MSW hazards, (ii) conserving energy and natural resources, (iii) reducing amounts of waste generated, and iv) managing waste in an environmentally-sound manner.

With the formation of the European Environmental Agency (EEA) in 1994, the European Commission subsequently set forth incremental reductions in municipal solid waste through the Landfill Directive of 1999; among other waste reduction indicators, by 2015, they set out to reduce the landfill of biodegradable products by 65%; and in a 2018 referendum, they set the goal of limiting the share of landfilled MSW to 10% by 2035. For example, Ireland has since exceeded the recommended 50% of recycled waste at 53% and has surpassed the broader 70% of material recovery (recycling and compostables) at 84%.

The coupled reduction and effective management of wastes are essential to sustainable development, and thus, climate change mitigation. It has been postulated that if all wastes could be recycled and reused for new materials and products, forming a ‘circular economy’ as opposed to a linear consumption model (i.e., take–make–dispose), this would typify sustainable development.

In part, the rote belief that waste disposal is linear (take–make–dispose), has been propelled by past systematic and cultural resistance in Western societies to reuse large quantities of waste and prevent potential sources of contamination. Thus, disposal to landfill has been the dominant disposal procedure for residues in North America and parts of Europe (excluding Switzerland, Germany, Finland, Sweden, and Belgium).

However, it is noteworthy that since 1995, the amount of waste disposed to landfill has decreased (62% in 1995 to 42% by 2017) for OECD (Organization for Economic Co-operation and Development) countries and in the U.S., as the reduction of waste at source, before it enters the waste stream, has become a high priority for state and local governments in recent years. Yunis and Aliakbari (2021) suggested that since Canada was generating less waste over time, the country has “partially decoupled waste generation from economic growth.”

Concomitantly, alternative methods for solid waste disposal are being adopted in countries with the luxury of sustainable development (i.e. Western societies), including: (i) biogas recovery from landfills, (ii) reuse and repurposing of post-consumer plastic (9% plastic recycling rate in Canada, 8.7% in the United States), (iii) quarry rehabilitation with leachate liners and caps for landfilled solid waste, and (iv) the land application of sewage biosolids for soil and crop nutrient amendment (McCarthy and Loyo, 2015). Nevertheless, current Western waste generation and management processes, operating among individual citizens through to entire corporations, remains largely linear and consumptive (Bowen et al., 2020).

Once municipal solid wastes are landfilled, these materials are subjected to the natural processes of decomposition (both anaerobic and aerobic), and can affect root systems, influence pore water and gas compositions in the unsaturated and saturated zones, and can have potentially deleterious effects on the aquatic and terrestrial environment. However, the effects are not limited to when wastes are disposed at a landfill. In the genesis of landfills, where landfills are placed is important as it renders the land unusable for the duration of landfill activities. They also degrade soil fertility and plant growth through the removal of organic and plant matter, destroy the soil profile, and disturb the ecological community at a site and beyond. Indeed, the broader effects of landfill include reduced ecosystem services (e.g., carbon sequestration in soil and biomass, bioremediation of

Fig. 1 Earl Bales Ski and Snow Board Centre in urban Toronto, Ontario. Courtesy City of Toronto, Parks Forestry and Recreation (2019) Retrieved from <https://www.toronto.ca/data/parks/prd/facilities/complex/2766/index.html>.

compounds); modification of watershed drainage routes, and change in vegetation patterns; reduced biodiversity, habitat fragmentation; and in select instances, mechanical (e.g., wind-blown litter into terrestrial and aquatic environments), and chemical (e.g., long-range transport of landfill gases through the atmospheric compartment, which are deposited in distant terrestrial and aquatic compartments) dispersion of pollutants. Even when landfills are capped, prior soil needs to be remediated and or allochthonous soil and matter may be introduced to the site (which involves degrading another site).

Through the advent and use of leachate liners in both Europe and North America, landfill sites have limited their potentially deleterious environmental effects and are often restored to new uses through capping (preventing atmospheric deposition of compounds) and revegetation. For example, in Toronto, Canada, the *Earl Bales Landfill* has been capped and converted into a city park and downhill ski hill (see Fig. 1), while another Toronto landfill has been capped and contoured to form a golf course (*BraeBen Golf Course*; formerly Britannia Landfill).

To understand the complex consequences of MSW application on soil systems (i.e., compost, land-application, landfilled), it is necessary to understand the production of municipal solid wastes, their composition and subsequent degradation, and ecotoxicological processes. Moreover, this chapter reviews how the potential for environmental impact of MSW is evaluated and remediated.

MSW production, composition, and elimination

Current MSW production in the western world

As world populations undergo development and demographic transition, the World Bank estimates that the amount of global waste is likely to grow from 2.01 Bt year⁻¹, to 2.59 Bt year⁻¹ in 2030, and 3.40 Bt year⁻¹ by 2050 (The World Bank (TWB), 2018). While there are current improvements in per capita efficiency of waste generation (as waste minimization), globally there is increasing waste creation overall (TWB, 2018), as can be seen in the U.S.: see Fig. 2 below. For example, in 1990, the U.S. generated 188.96 million tonnes, while in 2018, that figure had risen to 265.2 million tonnes.

The focus on increasing efficiency suggests that there already exists waste infrastructure to manage MSW effectively. However, today, nearly 46% of the global population is without basic waste management systems and that building systematic waste management capacity is needed first (TWB, 2018). Thus, most of the following information focusses on North American and Western European MSW strategies and their ongoing efforts to reduce the impact of MSW pollution to water, land, and air. Table 1 gives the proportion of recyclables, compostables, incinerated, and land-applied to landfill solid wastes by country for 2000 and 2018. The selected countries follow Manning's review (Manning, 2005) (Japan, United Kingdom, United States) with a current addition of Canada.

Ongoing MSW strategies

In the Western world, a waste management hierarchy has been strongly encouraged for the past few decades (Fig. 3), with a preferred strategy for managing and minimizing the impacts of MSW. Source reduction and reuse, or the prevention of waste in the first place,

is being implemented at the manufacturing, consumer, and institutional level. While recycling has been practiced, it has had varying degrees of success in waste reduction for the past half century. As of 2018, the USEPA reported 62.5 million tonnes of MSW was recycled, or less than 25% of the total MSW generated (265.2 million tonnes).

Recyclable and reclamation products

Recyclable municipal solid waste is that diverted from traditional solid waste disposal streams (e.g., land-application, landfill, incineration) for meaningful reuse and repurposing. Troschinetz and Mihelcic (2009) identified some of the barriers to adoption of MSW recycling, including: (i) waste collection and segregation, (ii) household education, (iii) technological and human abilities, and (iv) government policy. These concerns are ratified in the USEPA *National Recycling Strategy* which prioritizes (i) the market for recycled materials, (ii) collection and materials sorting infrastructure, and (iii) building education capacity and policies which reduce contamination in recyclable material streams, while promoting circularity.

Recyclable wastes are post-consumer products, such as plastics, that are transformed and remanufactured into new products with productive use. The United States reports that of the 62.6 million tonnes recycled, 66% is paper and paperboard, while plastic represents 4.4% of all redirected material (Fig. 4). In Canada, 3 million tonnes of plastic wastes are produced annually; however, only ~290 thousand tonnes are recycled (roughly 9%). What is necessary are systems to deal with the diversity of recyclable products. These include paper products (e.g., packaging, cardboard, newsprint, and office paper), containers (ferrous metal cans and vessels, aluminum, glass, plastics, and composites of the aforementioned sources), household hazardous wastes (e.g., paints, pesticides, and unregulated hazardous wastes), construction and demolition debris, batteries, computers and other electronics ('e-wastes'), used tires, oil and oil filters, and discarded appliances that are difficult-to-process and require niche reclamation technologies.

Recyclable products are collected from households and industrial and commercial sources in a variety of ways, including: (i) dedicated recyclable curbside collection (commingled or source-separated), (ii) collected with MSW and sorted at facilities, (iii) user-delivered to facilities through purchase (e.g., as buy-back) or donation programs, and (iv) through individual disposal agreements from industrial and commercial waste generators.

Once collected, wastes are recycled differentially. Primary mechanical recycling involves material that is shredded and melted into new pellets to make new products of similar quality. Secondary recovery involves processing reused material into products with lower qualities (i.e., lower grade plastics (i.e., downgrading)). Tertiary recovery involves extracting chemical constituents (i.e., chemical or feedstock recycling to depolymerize polymers). Quaternary recovery involves extracting energy from the product (i.e., energy-from-waste processes such as valorization). The multiple types of recycling above are ranked in decreasing order of societal value, given the reliance on raw materials (Hopewell et al., 2009). Newer biodegradable plastics are decomposed similarly to putrescible wastes, as the products are composed of large starch and cellulose concentrations, requiring decomposition from lignocellulosic bacteria and fungi in either aerobic and or anaerobic digestion systems).

Organic waste and compost strategies

Organic (putrescible) waste from food processing and consumption, in addition to collected leaf litter and garden waste, are considered. Compostable MSW from households and businesses is collected and managed in localized waste management units (e.g., municipalities in Canada, United States and Europe) and brought to industrial composting facilities. Selectively, compostables are remediated on-site by homeowners or local groups when municipality-led disposal is not available (e.g., backyard aerobic composters).

At industrial facilities, organic waste is decomposed either by aerobic (i.e., oxygen-rich putrefaction) or anaerobic mechanisms (i.e., anoxic or oxygen-poor decomposition). Typically, households compost aerobically. When MSW is delivered to composting

Fig. 4 Total MSW Recycling in 2018, by Material, Courtesy USEPA (2018). Note, units are provided in U.S tons (i.e., 69.1 million U.S. tons = 62.7 million tonnes). United States Environmental Protection Agency (2018) *National Recycling Strategy: Part One of a Series on Building a Circular Economy for All*. Retrieved from: <https://www.epa.gov/system/files/documents/2021-11/final-national-recycling-strategy.pdf>.

facilities, the substrate is sorted to remove non-compostable objects (e.g., plastics, non-putrescible wastes generally), and is prepared for primary composting through mechanical processes (i.e., grinding or shredding). Organic wastes may be primed for subsequent chemical and biological processes through adding leachate, water, and or inoculants such as bacteria (i.e., actinomycetes) and fungi (organisms specifically evolved to degrade more recalcitrant compounds and fixing nitrogen). While inoculants vary depending on geography and by the composition of organic matter, they predominantly include *Trichoderma* sp. (fungi producing cellulase and chitinase, degrading carbohydrates, and controlling pathogenicity, respectively) and *Pleurotus* sp. (i.e., spent mushroom substrate (SMS), or 'white rot,' decomposing lignin, cellulose, and hemicellulose materials from paper products and lawn wastes). Moreover, biological inoculation with microbiota is a conservative process, as wastes from digesters are used as bacterial and fungal community cultivars in subsequent composting. Collectively, mechanical, and chemical processes, in addition to microbial inoculation, improve the efficiency of decomposition.

During aerobic decomposition, the heat released from biological activity typically regulates pathogenic abundance to acceptable limits. Composts are typically placed into oxygen-rich environments (i.e., windrows) to be cured, where microorganisms (i.e., either atmospherically-deposited or from initial inoculation) slowly metabolize organic carbon into carbon dioxide and soil humus, and fix atmospheric nitrogen into soil nitrates to produce collectively a nutrient-rich organic matter. During curing, microorganisms such as thermophilic fungi (i.e., white-rot'), continue to break down more complex lignocellulosic structures. The compost is screened to reduce material size and remove relict physical contaminants (e.g., glass, metal) and stored until used. Nevertheless, there is potential for soil and water contamination through land application of compostables for soil and crop nutrient amendment. There are benefits to soil through increasing organic matter (i.e., source of carbon for plant development, improved water retention capacity), and the addition of soil macronutrients (i.e., N (nitrogen), P (phosphorus), K (potassium), and S (sulfur)). However, there is always potential, albeit mostly negligible, for the introduction of contaminants and physical litter that was not sufficiently screened and pre-processed (e.g., microplastics).

Under anoxic (i.e., oxygen-deprived) decomposition conditions, putrescible wastes are typically processed within high-solids systems (moisture content less than 80%) or low-solids (or wet systems) (moisture content above 80%). Furthermore, within each category, anaerobic digestion can occur within single or multiple stage processes. Within a multi-stage process, primary decomposition occurs in an acidic (pH 5–6) environment to allow for lignocellulose degradation (e.g., using *Cellulomonas* sp. and *Clostridium* sp. bacteria) and the creation of acetates and hydrogen (e.g., *Syntrophomonas* and *Syntrophobacter* genera). Subsequently, the feedstock is transferred to another vessel, and the pH is raised to neutral (~6.2–7) to optimize the transformation of methane gas by methanogens (e.g., heterotrophic methane bacteria convert acetic acid (CH_3COOH) into methane gas (CH_4)) (Verstraete et al., 2002). While methane gas production can occur in a single stage, the sole decomposition environment means that neither step (i.e., acidogenesis for acetate production, or methanogenesis) is optimized. The resulting methane gas may be used for heat and to power engines. The digestives (the settled products of anaerobic digestion) may be reused within inoculation of the digester (introducing decomposition bacteria from the end of one batch into the beginning of another).

Similar to aerobic digestives, anaerobic digestives may be stabilized and land-applied, either for soil and crop nutrient amendment, or brownfield remediation. With regard to potential soil contamination, anaerobic digestion typically further degrades more recalcitrant and persistent compounds, thus posing less ecotoxicological risk to soil ecosystems.

Energy recovery

In 2015, the European Commission presented a Circular Economy Package to the European Parliament to promote a shift from a linear economy, where resources have traditionally been extracted, used, and subsequently disposed of as waste. In this document, it was strongly recommended that the use of materials, and waste generation be minimized, which could be achieved through source minimization, reclamation and recycling of discarded products, composting of organic biomass, and energy recovery from MSW to become a renewable energy source (EUC, 2015). Energy can be recovered from waste by landfill gas recovery, combustion, pyrolyzation and gasification, and anaerobic digestion in processes that convert non-recyclable waste into useable heat, electricity, or fuel. The European Commission further suggested that this renewable energy could contribute 27% by 2030 to the final energy production budget. Energy recovery from MSW can provide a local source of renewable energy while the overall volume of waste being disposed of in landfills is reduced. In addition, the waste-to-energy (WtE) strategy, as a source of renewable energy, is expected to contribute to a reduction in the dependency on fossil fuel use, leading to a reduction in GHG (greenhouse gas) emissions. The number of WtE facilities for MSW in 2016 was 1618 plants globally, with 512 plants in Europe, 822 plants in Japan, and 88 in the United States (Scarlat et al., 2019).

In the U.S., combustion of MSW was initiated in the late 1880s and as a very primitive form of energy-from-waste, the heat generated from the incinerators was used to boil water that subsequently powered steam generators to generate electricity to be used domestically and in industrial processes. However, by the 1960s, the impact on air and water quality from these incinerators led to the Clean Air Act of 1970, with regulations to control emissions. While the combustion of MSW increased through the 1980s with cleaner emissions, and with 34 million tons of MSW diverted to WtE processes by 2017, landfill is still considered a more viable, albeit short-term, option in America as space limitations are not as important as in smaller countries such as Japan and some European nations. In addition, public opposition and the significant initial funding needed to build combustion plants for energy recovery, is slowing the implementation of WtE facilities further in North America.

The critical need for the increased development of WtE facilities globally cannot be overstated when dependence on traditional fossil fuels for energy is no longer sustainable. Thus, while prior sections described the essential need for recycling and composting

as the second tier of the MSW hierarchy (see Fig. 3), energy recovery from waste is an important third component that includes landfill gas utilization, incineration with energy recovery, pyrolysis and gasification, and anaerobic digestion with biogas production.

Landfill gas (LFG) utilization

In regions of the world where land is perceived as abundant (Canada, United States, etc.), MSW is often disposed in landfills. When biogenic components of that waste (paper fiber, food waste, wood, etc.) are buried, a complex series of reactions occurs and anaerobic microorganisms degrade the organic matter to produce landfill gas (LFG) composed primarily of methane (40–60%) and carbon dioxide, with trace amounts of volatile organic compounds (VOCs) providing less than 1% of the remaining gas components (Sullivan, 2010). After fossil fuel combustion and agriculture, landfills produce the third largest anthropogenic source of methane in the U.S. and as a potent GHG, this compound must be captured and changed to a less destructive form. While controlling its emission is crucial, the ability to use captured methane to generate energy is a sustainable strategy that is being implemented in many regions, especially in North America.

The capture, collection, and processing of methane from landfills for multiple purposes is shown in Fig. 5. Vertical and horizontal wells are installed into the MSW where 67% (open landfills) to 84% (closed landfills) of the gas is extracted and piped to a main collection system where it is flared (burned off) or treated for beneficial use, including industrial and institutional uses, arts and crafts, pipeline gas, and vehicle fuel. When landfill gas cannot be used for beneficial use, it is flared off to become relatively harmless carbon dioxide. However, for beneficial use, including pipeline gas, the methane must be treated to remove impurities, with primary treatment removing moisture and particulates and secondary treatment implemented to remove siloxanes and sulfur compounds that can damage equipment. The landfill gas can be sent in pipelines to boilers and kilns, to be used similarly to natural gas, or to provide heat and power to local greenhouses. In addition, artists' studios engaged in glass-blowing, metal-working, or pottery that are energy-intensive can use this beneficial energy source and gas turbines can produce electricity to sell commercially or to be used on-site.

Thermal waste-to-energy (WtE)

In regions of the world where land constraints dictate against significant landfill strategies, MSW is often diverted to WtE facilities, where cogeneration incineration, or incineration with energy recovery, is often the prevalent strategy, particularly in Japan (80% MSW was combusted in 2015) and the European Union (Kaza and Bhada-Tata, 2018). Advanced thermal treatment, including pyrolysis and gasification, and the anaerobic digestion of biodegradable waste, are also significant WtE processes (Scarlat et al., 2019). In a 2019 report, the International Environmental Technology Centre (IETC) of the United Nations Environmental

Fig. 5 Landfill gas collection, processing, and beneficial uses of methane. Courtesy United States Environmental Protection Agency (2021) *Basic Information about Landfill Gas*. Retrieved from: <https://www.epa.gov/lmop/basic-information-about-landfill-gas>.

Programme (UNEP) stated that over 1700 thermal WtE facilities are in operation worldwide, with 80% of the plants located in developed countries, and that 200 thermal WtE plants are under construction in developing countries (UNEP, 2019).

Combustion (incineration) with energy recovery

The MSW is the waste feedstock during the incineration process where the volume of waste can be reduced by 90% and where GHG emissions are reduced by diverting waste from landfills and open burning. Concerns about toxic emissions from modern incinerators, including dioxins, furans, and mercury, have been addressed with advanced air pollution control (APC) strategies that are implemented in countries with WtE facilities. The waste is combusted under controlled conditions and electricity and/or heat are subsequently generated, together with non-toxic bottom ash and toxic fly ash. The bottom ash, which usually is composed of silica, quartz, calcium, iron oxide, and aluminum oxide, can be recycled as construction material or used in the production of cement, while fly ash often contains a high content of 'heavy' metals and is disposed of in a hazardous waste landfill (UNEP, 2019). In the European Union, cogeneration data suggest that both electricity (500 kWh t^{-1}) and heat (1000 kWh t^{-1}) can be generated for industrial and district heating. Pollution from toxic emissions is reported to be low due to a combination of high temperature combustion that destroys most organic compounds, advanced air pollution control systems, and typically strict government emission regulations (Kaza and Bhada-Tata, 2018). Although incineration technology has advanced in the past decades, it is still a relatively expensive strategy and is used primarily in high-income countries where high technical capacity exists with strong environmental regulations. European Union countries with the largest capacities for MSW incineration are led by Germany (24 million tonnes) and France (16 million tonnes), followed by Sweden, Netherlands, Denmark, Norway, and Austria (Scarlat et al., 2019). In 2018, 30.8 million tonnes of MSW were combusted in the U.S. for energy recovery.

Pyrolysis and gasification

Advanced thermal treatment (ATT) technologies such as pyrolysis and gasification convert MSW not into heat and electricity (incineration energy recovery) but into synthetic gas (syngas) or liquid fuel such as tar or a solid material (char) that can be used as a soil amendment (Kaza and Bhada-Tata, 2018). The resulting syngas is largely composed of hydrogen (H_2) and carbon monoxide (CO) and is itself a fuel due to the flammability of H_2 and CO . It can be used as the hydrogen source in fuel cells, because high-temperature solid oxide fuel cells can use the gas mixtures, including carbon dioxide and methane, produced by gasification. Pyrolysis involves high temperature heating of MSW in oxygen-free environments; higher temperatures ($>760^\circ\text{C}$) produce more syngas and lower temperatures ($450\text{--}730^\circ\text{C}$) generate both liquid fuel and gas. Gasification also involves high temperatures in an environment containing some oxygen (O_2), but not as much O_2 as that required for incineration (Kaza and Bhada-Tata, 2018). Syngas can be used to produce electricity, or further processed to remove contaminants such as chloride and potassium to produce vehicle fuel.

While the use of MSW or biosolids in gasification processes to produce energy from waste is, in principle, sound, there are few instances globally of successful MSW facilities that use this strategy. Gasification is not new; heating organic matter or fossil fuels such as coal in a high temperature environment with a controlled amount of oxygen has been used to supply energy since the 1800s. However, a reliable feedstock that is of a consistent quality is difficult to obtain from MSW as it is a mixed composite of various products, and upstream separation of waste to secure a constant waste composition is necessary. Most pyrolysis and gasification plants initially pretreat incoming MSW feedstock by drying, sterilizing, and separation of recyclables. The remaining waste is then heated to produce the syngas, tar, and char, with the former being cleaned to remove particles and soluble substances to produce a 'clean gas' for electricity generation and/or heat (Kaza and Bhada-Tata, 2018).

The benefits of advanced thermal treatment technologies are substantial because the process diverts MSW from landfills, reduces methane emissions, and the char produced is an important soil fertility amendment. However, the technologies are relatively new; for instance, only a few full-scale operations exist in Japan and Europe where advanced technical knowledge and financial resources are available (Kaza and Bhada-Tata, 2018).

Non-thermal waste-to-energy (WtE) (anaerobic digestion)

Processes to convert food and outdoor green waste into fertilizers and biogas have been discussed under composting procedures that use oxygen, and anaerobic systems that exclude oxygen. More information on energy recovery during anaerobic digestion is provided here. In the absence of oxygen, anaerobic microorganisms degrade the organic components and produce a semi-solid fertilizer and biogas (Fig. 6). The process is in a closed vessel, or reactor, which allows a feedstock containing many materials such as manure, biosolids, and MSW biomass to co-digest. This anaerobic digestion process typically reduces the waste feedstock by 50% while conserving nutrients and killing up to 95% of pathogenic microbes. The biogas can be used to generate electricity or be further refined to supply natural gas (Kaza and Bhada-Tata, 2018).

The biogas produced is primarily methane (50–75%), a natural gas, and can be used to provide heat, generate electricity, and power cooling systems. In addition, biogas can be further purified to remove carbon dioxide (CO_2), hydrogen sulfide (H_2S), and water to generate renewable natural gas (RNG). After appropriate treatment (including drying), the digestate can be used as a nutrient-rich fertilizer, animal bedding, or as a foundation for bioplastics, among other uses. Anaerobic digestion of MSW is used extensively in Europe and is becoming economically feasible as source separation practices improve. With increasingly high landfill disposal costs, and favorable energy prices, non-thermal Waste-to-Energy (WtE) practices are expanding globally (Kaza and Bhada-Tata, 2018).

Fig. 6 Feedstock from agriculture, wastewater treatment plants, MSW, other industries undergo anaerobic digestion to produce biogas and digestate that can be used for fertilizers and other beneficial uses. Courtesy United States Environmental Protection Agency (2019) *Methane Emissions in the United States: Sources, Solutions & Opportunities for Reductions*. https://www.epa.gov/sites/default/files/2019-06/documents/methane_emissions_overview_may2019.pdf.

Treatment and disposal: Landfill

The MSW that is unable to be composted or recycled, either because of its composition or the lack of capacity to do so (i.e., insufficient waste management infrastructure), or not utilized in WtE facilities requires final disposal. In North America, these MSWs are disposed of to landfill or are incinerated. In the United States, the USEPA estimates 67.9% of MSW is either sent to landfill (56.1%) or incinerated (11.8%). These solid wastes are collected similarly to recycled wastes through curbside household collection and individual generator disposal agreements.

When solid wastes are landfilled, they are presumed to be localized and geographically constrained (Sivakumar-Babu et al., 2017). Landfill typically involves daily compaction of the surface with new wastes until capping (i.e., sealing a completed landfill), in turn, anaerobic conditions are established for waste degradation, similar to composting. However, there is potential for widespread environmental impact if leachate (i.e., contaminated precipitation through contact with wastes) is not contained and or unprocessed and enters watercourses, surface water, permeates soil (through infiltration and percolation), and subsequently groundwater. Leachates characteristically contain a large amount of organic matter (OM), have low pH (acidic with carbonic acid and basic with ammonium), chemical oxygen demand (COD), ammonia (NH_4), nitrogen gas (N_2), and metals (e.g., mercury (Hg)), in addition to other emerging contaminants of concern (ESOCs). Prior to discharge, OM is removed from leachate, as determined by the degree of chemical and biological oxygen demand (COD, BOD respectively) and ammonium content, to avoid potential toxicity to aquatic and terrestrial environments.

The composition of landfill leachate is typically characterized by age; for instance, younger landfill leachate has products of acidogenic anaerobic decomposition (where acidifying bacteria convert hydrolysis products and soluble chemicals into short-chain acids, alcohols, hydrogen, aldehydes, and carbon dioxide). Moreover, younger leachate may contain volatile fatty acids (VFAs) because of large amounts of biodegradable matter, and the high moisture content in landfilled waste (Welander et al., 1997). By comparison, mature landfill materials are further along the decomposition process where methanogenic microorganisms will transform acetate ($\text{C}_2\text{H}_3\text{O}_2$) and hydrogen (H_2) into CH_4 (methane) and carbon dioxide (CO_2), which are then emitted to the atmosphere. The remaining leachate is dominated by non-biodegradable humic substances. As gas creation from leachate is a potential source of atmospheric contamination, engineered solutions capture end-member gases (e.g., methane, carbon dioxide) for energy production. Apart from leachate-derived gas production, the other landfill gases are reported in low proportions and vary because they depend upon what wastes are discarded (atmospheric nitrogen (N_2), hydrogen (H_2), carbon monoxide (CO), and hydrogen sulfide (H_2S) (Manning, 2005). While gas production directly affects atmospheric compartments, it results in the indirect effects of the long-range transport of pollutants, which are subsequently precipitated onto terrestrial (including soil) and aquatic environments.

Newer landfills typically collect and treat leachate, either on-site or at wastewater treatment facilities, to mitigate potential deleterious environmental effects. Treated singly and concomitantly, leachate is processed similarly to sewage treatment through

(i) aerobic biological systems, such as activated sludge or aerated lagoons, (ii) anaerobic biological systems, such as bioreactors or anoxic lagoons, (iii) physicochemical treatment, where environmental properties are modified for optimal degradation (e.g., pH adjustments, deoxygenation, chemical precipitation, reduction and oxidation); and or (iv) coagulation using binders (e.g., lime, ferric chloride, electrical systems).

Treatment and disposal: Incineration

When incinerated, the volume of waste is significantly reduced. Historically, air pollution from incineration was of potential concern. Modern incinerators typically include scrubbers and other strategies to prevent atmospheric contamination. For instance, scrubbers exist for many persistent organic pollutants (POPs) such as carcinogenic dioxins (i.e., polychlorinated dibenzodioxins) and furans, in addition to metals (e.g., Hg, Fe, Pb) (Zhang et al., 2020).

Incineration typically occurs in waste-to-energy facilities (WtE) and wastewater sludge incinerators (e.g., incineration of sludge); however, the exact energy potential depends on the composition of the waste or dried sludge (e.g., 7,594,390 J kg⁻¹ for food waste to 101,874,148 J kg⁻¹ for polypropylene products (i.e., plastics) (Tillman, 2012). As a result of combustion, predominant compounds include silicon (Si), aluminum (Al), iron (Fe), calcium (Ca), magnesium (Mg), potassium (K), sodium (Na), and chlorine (Cl), in addition to the metals cadmium (Cd), chromium (Cr), copper (Cu), mercury (Hg), nickel (Ni), lead (Pb), and zinc (Zn). Furthermore, common volatile organic compounds (VOCs) of methylene (CH₂), CO, CO₂, CH₄, ethane (C₂H₆), and amino radicals (i.e., amide ion, NH₂), in addition to water vapor (H₂O(g)) are common (Tillman, 2012). Similarly, the exact gases released are contingent on the source material, necessitating understanding of the chemistry of different combustibles (i.e. source compounds, interactions, end members) (Tillman, 2012). Finally, the ash from incineration may be recovered for iron (i.e. as 'ferrous recovery') and other metals (as a form of tertiary recovery) or sent for disposal.

Incineration gases can be cleaned by (i) separation processes (i.e., washing, leaching, electrochemical processes, thermal treatment, flocculation and filtration, ion exchange, crystallization, and evaporation to transform gas products to non-environmentally-deleterious compounds before they are re-emitted into the atmosphere), (ii) solidification and stabilization (i.e. stabilization with and without additives, binders, or macro-encapsulation), and (iii) thermal methods (vitrification, sintering, and fusion) (see Van der Sloot et al., 2001, for review). For example, limestone (calcium carbonate and dolomite) is popularly used for the removal of hydrochloric acid (HCl) and sulfur dioxide (SO₂) as a form of stabilization with additives.

Biosolids (i.e., processed sewage sludge)

Biosolids (or sewage sludge) are a major by-product of primary and secondary treatment of residential and industrial effluent in wastewater treatment plants (Puddephatt et al., 2022). Biosolids are created in similar ways to the processing of landfill leachate, and disposed of similarly to other solid wastes (including incineration and landfilling). The treated product is also used similarly to decomposed putrescible matter in their land-application for soil and crop nutrient amendment and remediating brownfields (similar to compostables). Biosolids are characteristically high in organic matter (OM) and soil macronutrients such as phosphorus (P), nitrogen (N), potassium (K), and sulfur (S), and are applied as liquids or solid composites to land. In 2012, Canada produced more than 660,000 metric tons (dry weight, dw) of biosolids, with almost half of them being produced in southern Ontario. In the United States, 51% of biosolids were disposed through land-application, 22% were landfilled, 16% incinerated, and 11% were subject to other management practices (e.g., brownfield remediation, sold to the public for lawn and garden soil amendments, etc.).

As a by-product of wastewater treatment, there are often engineered strategies to remove organic contaminants (e.g., flame retardants, personal pharmaceuticals and care products (PPCPs), potentially toxic metals (e.g. mercury, lead), and pathogens (e.g. enteroviruses, *Salmonella* sp., *Listeria* sp., and protists such as *Giardia*) from sewage sludge (Flemming et al., 2017). See McCarthy and Loyo (2015), for a review of the production and treatments of biosolids. Many of the compounds found in trace amounts, and predominantly studied in biosolids, are emerging substances of concern (ESOCs). While ESOCs are ambiguously defined, there is consensus on the common characteristics including i) that they have been detected in at least one environmental compartment (i.e., terrestrial, aquatic, atmospheric) and are present in relatively small (trace) amounts and ii) that they are generally not being regulated, or at least not for a recent concern, such as possible endocrine disruptor effects of poly-chlorinated bisphenols (PCBs), which were banned because of their persistent and toxic nature (San Francisco Estuary Institute (SFEI), 2013).

At wastewater treatment plants, incoming wastewater from sanitary networks is treated through physical, mechanical, chemical, and biological means in two stages of primary and secondary treatment. Primary treatment is a physical process where heavier solids (e.g., tree branches, rocks, and feces) are removed; secondary treatment is a biological process where organic pollutants in effluent are oxidized. Moreover, during secondary treatment, the addition of chemicals may be used to precipitate and coagulate macronutrients from the secondary wastewater (aluminum sulfate (Al₂(SO₄)₃) or calcium hydroxide (Ca(OH)₂)). Once settled, the solids (or sludge) in both primary and secondary treatment processes are sent to a digester where organic matter, ammonia, and amino species are converted to carbon dioxide, water, and nitrate.

Biosolids are also produced using anaerobic digestion and dewatering, where anoxic microorganisms continue to break down the organic material present in the original sludge and create a product much less offensive in terms of odor and organic contaminants. In the anaerobic digestion process, the four microorganism groups (hydrolyzers, acidogens, acetogens, and subsequently, methanogens) convert lignocellulosic compounds and suspended solids to organic acids, then into acetate and hydrogen (H₂), which are subsequently evolved into the more stable compounds of carbon dioxide (CO₂), ammonia (NH₃), and methane (CH₄). In both aerobic and anaerobic digestion, the volume of sludge, and abundance of pathogens (approximately 95% removal) is reduced from the source sludge (Toronto Water, 2019). At a subsequent stage, dewatering reduces water content and pathogens in

the resulting biosolids. Dewatering is a mechanical process where the addition of chemicals releases water bound to organic matter, which is then removed by centrifugation, pressing, or belts. The newly formed biosolids, with a reduced pathogen and volatile organic compounds (VOCs) load, are then applied to land, incinerated, or disposed of in landfills.

The MSW challenges

Globally, an estimated 2 billion tonnes of MSW were generated in 2016 and projected to increase to 3.4 billion tonnes by 2050, if current practices of MSW production continue (Kaza et al., 2018). Approximately 37% of waste is landfilled, 33% is openly dumped, 19% is recycled and composted, and 11% undergoes modern incineration with energy recovery. Adequate waste disposal or treatment is almost exclusively the domain of high- and upper-middle-income countries while lower-income countries rely on open-dumping (93% compared to only 2% in high-income countries) (Kaza et al., 2018). In addition, high-income countries, despite education and government incentives, continue to generate large amounts of MSW. In the United States, the generation of MSW has increased from 79.92 million tonnes in 1960, to 264.9 million tonnes in 2018, translating into a generation rate of 1.2 kgs/person/day in 1960, to 2.3 kgs/person/day, respectively. This increase has occurred despite comprehensive efforts on source reduction and use, recycling and composting, and energy recovery from combustion (zero in 1960; 12% in 2018). In Europe, while increasingly sophisticated engineered technologies have seen the rise of WtE facilities, Scarlat et al. (2019) report that MSW as an energy source is underexploited in most European countries, with only a very small percentage of the existing waste being converted to energy. Lastly, low-income countries are expected to increase their waste generation by more than three times by 2050, with open-dumping speculated to remain the major strategy of disposal (Kaza et al., 2018).

Effective waste management and disposal practices will, and has been, affected by natural and anthropogenic disasters (i.e., hurricanes, earthquakes, floods, tornadoes, forest fires, pandemics and war). While the immediate effect of such calamities will be obvious, infrastructure to support MSW strategies will be influenced negatively, including stewardship of long-term landfills and the continuation of WtE facilities. Municipal policies focused on MSW source reduction, reuse and recycle plans, and composting options will also, out of necessity for preserving human life, be reduced. In response, the United States Environmental Protection Agency continues to develop plans for MSW preparedness in the face of disastrous weather events, including the need to deal with huge amounts of storm debris and flood residues properly. Other catastrophic events such as chemical accidents and domestic security attacks similarly pose additional challenges for municipalities globally.

Concluding remarks

The World Business Council for Sustainable Development (WBCSD), in their *Vision 2050 – The New Agenda for Business Report*, suggest that the projected 9 billion people by 2050 must learn to live within the limits of the resources of Planet Earth. The report further proposes that material demand, consumption, and production become transformed strategies to address the truth – that non-renewable resources are truly limited. Thus, practices that mandate closed-loop recycling make the concept of the obsolescence of waste a normalized business practice (WBCSD, 2021).

In support, the 2015 European Commission's Report to the European Parliament outlined the necessity for a circular economy in the waste management field, similarly stipulating a multinational plan for waste and resource management. Strategies include source minimization, reclamation and recycling of discarded products to be reengineered for multiple purposes including raw materials for manufacturing, composting of organic matter, and energy recovery to become a renewable energy source, have all been described. The reduction in GHG emissions and a decrease in energy and water use are mandatory in this circular economy plan (UNEP, 2019). Lastly, in the United States, new attitudes and technological advances in life-cycle product development, use, and retirement are ushering in a new era of 'waste avoidance,' rather than current strategies of 'waste management,' through improved design and reuse and recycling mandates.

The effects of MSW disposal on their environment are broadly similar to the solutions we need to reduce and close the loop on otherwise unsustainable and unprincipled resource consumption: these are to consider the broader socio-political and environmental system on which they depend. Thus, solutions need be transboundary and they need to invoke principles of 'strong sustainability,' which principally involves changing Western consumption patterns through education and incentivization, ultimately bringing about large-scale behavior changes. Finally, these solutions need to support research and innovation to improve the efficiency of existing recycling and composting processes.

Abstract

Various remediation approaches have been demonstrated for the management of metal and organic contaminants. Remediation approaches may be broadly categorized as “Isolation,” “Immobilization” “Degradation/toxicity reduction.” The feasibility (effectiveness, cost) of any given approach depends on the nature of contamination and site-specific conditions and constraints. The chosen remediation technology must render the site suitable for the future proposed land use. Increasingly, consideration of sustainability has led to emphasis on risk-based approaches which seek to reduce risks to human health and ecosystems to ensure contaminated land is made suitable for a proposed future land use.

Key points

- A range of technologies is available for the remediation of metals and organic contaminants
- Remediation techniques may be categorized as “Isolation,” “Immobilization” “Degradation/toxicity reduction”
- Applicability of remediation approaches depends on the contaminants of concern and site-specific considerations
- Some technologies are applied in situ and some require ex situ treatment of soil

Introduction

Widespread contamination of land has resulted from human activities such as mining, industrial and energy production, agriculture, transport, and waste generation and disposal. This contamination is often attributed to the emission and exposure of “heavy” metals, metalloids and a wide spectrum of organic and other inorganic compounds. Among metals and metalloids, lead (Pb), arsenic (As), chromium (Cr), cadmium (Cd), mercury (Hg), copper (Cu), nickel (Ni), zinc (Zn) and antimony (Sb) are priority elements of potential concern for ecological and human health. Similarly, in the case of organic contaminants, petroleum hydrocarbons, polycyclic aromatic hydrocarbons (PAHs), trichloroethylene (TCE), polychlorinated biphenyl (PCBs), dioxins, pentachlorophenol (PCP), perfluoroalkyl and polyfluoroalkyl substances (PFAS), and dichlorodiphenyltrichloroethane (DDT) are commonly found soil contaminants.

Remediation of contaminated soils is a critical part of the restoration of degraded lands to safe and beneficial reuse. This is becoming increasingly important as urban populations are expanding into areas that were previously used for industries and agriculture.

It is recognized that a sustainable risk-based approach is needed to tackle the scale of this issue. A risk-based approach seeks to reduce risks to human health and ecosystems associated with contaminated land so that they are suitable for a proposed future land use.

Recent decades have seen extensive research and development on remediation approaches and technologies. Many conventional remediation technologies, such as “pump and treat,” capping and containment, solidification and stabilization, soil washing, thermal treatment, in situ chemical oxidation, and in situ biodegradation are being applied commercially, while improvements to existing technologies and development of new approaches continue. An emphasis on sustainability is increasingly placed on remediation technologies considering the site and contaminants characteristics. Approaches, such as excavation and disposal of contaminated soil to landfill are becoming more undesirable.

Broadly, remediation technologies fall into the categories “containment and isolation,” “immobilization,” “separation and degradation” and “detoxification.”

Remediation approaches

Table 1 provides an overview of the main remediation techniques and their application.

Capping

Capping is the process of covering contaminated soil or landfill waste to create a barrier to the hazardous materials. It is a non-removal soil remediation approach that does not destroy or remove the contaminants, but keeps them in place. Caps isolate the contaminants to prevent them from spreading further, though there remains risk of exposure and mobilization where the integrity of the cap and liners is not preserved and in the future beyond the lifetime of the containment layers. Capping techniques can be utilized for a variety of reasons, including restricting access of contaminant to people and wildlife, reducing water percolation from site of concern, preventing the escape of gases containing harmful volatile chemicals, and stopping hazardous material from being blown by the wind.

Selection of an appropriate capping system depends on the contaminant’s characteristics, the size of the site, rainfall, and future use. A cap can be made simply by placing a single layer of material over mildly contaminated soil. However, highly contaminated soil or hazardous waste landfill may require several layers of different materials, including a vegetative layer, drainage layer, geomembrane, and clay layer (Fig. 1). The clay layer acts as the barrier because of its low permeability, which is sometimes coupled with a geo-synthetic membrane to make it more effective (US EPA, 2012a).

Capping of contaminated areas is one of the most simple, rapid, and cost-effective solutions for reducing risks from soil contamination. However, it is not a permanent remediation solution because the contamination remains, and caps and geomembranes can deteriorate over time. In addition, the seasonal fluctuation of groundwater at the capping site, as well as surrounding hydrogeological features must be considered. These may influence the cap stability. Furthermore, the risk of slippage must be assessed if a cap is installed on sloping land (Liu et al., 2018).

Table 1 Overview of soil remediation approaches.

Category	Techniques	Processes	Contaminants susceptible to the technique	Advantages	Limitations
Isolation	Capping, Containment Cells and Sub-surface barriers	Physical	Metals and organics	Simple, rapid and cost-effective	Contamination remains on site and needs to be monitored
Immobilization	Solidification and Chemical Stabilization	Physical and Chemical	Metal(loid)s and organics	Low cost; can be both in situ and ex situ	Requires binding materials; Long-term stability requires consideration of other factors (e.g., dosage and regeneration of binding material)
Degradation/toxicity reduction	Bioremediation, Phytoremediation, Soil Washing, Chemical Reduction/Oxidation, Electrokinetic, Thermal Treatment and Soil Vapor Extraction	Biological, Chemical and Physical	Metal(loid)s and organics	Applicability and feasibility depend upon contaminant and site-specific conditions

Engineered containment cells

Engineered containment cells (ECCs) are designed to contain wastes and contaminated soil completely on site. They provide a more fully engineered approach than capping alone by limiting infiltration and providing a full contaminant barrier between the contaminated substances and the clean soil at the site (Fig. 2). This method of remediation depends on a feasibility assessment whether the contaminants identified require temporary or permanent containment rather than their destruction or removal (CRC CARE, 2019a).

An ECC needs a layer of poorly permeable or impermeable material as a barrier on the sides and bottom surface of the containment cell. Clay, such as bentonite or a mixture of clay and soil is often used as the barrier layer or "geo membrane." The ECCs also use an engineered cap for limiting infiltration and exposure of contaminants within the cell. An engineered cap may include a layer of vegetation to stabilize the capping layer, along with providing phytoremediation (US-EPA, 2012b). An ECC differs from other engineered barriers such as vertical engineered barriers (VEBs) which are installed vertically in the subsurface in trenches for containing the contaminants at their origin (in situ). On the other hand, ECCs are typically used to consolidate and contain excavated material from sites.

This remediation method is a choice of technology where the clean-up of contaminants would be expensive and technically difficult to execute. Landfill or active metal smelter sites may be examples of such target land sites.

Soil stabilization/solidification

Stabilization/solidification (S/S) refers to as a remediation technology whereby the mobility of contaminants is contained or restricted using binding materials. These binding materials can be cementitious and or might include additional stabilizing materials such as biochar, modified clays, iron nanoparticles, slag.

Fig. 2 Engineered containment barrier of contaminated soil. Scheme adapted after US-EPA (2012b) A Citizen's Guide to Engineered Vertical Barriers. In: Agency, E. P. (ed.). EPA.

Stabilization is the process where a chemical reaction is expected between the modifier and contaminant(s) of concern, aiming to cease or minimize the leachability and volatilization of those contaminants. On the other hand, solidification is defined as the process where the remediating material entraps or encapsulates the contaminants into its physical matrix. However, these two approaches are often combined in the process, and are thus historically known as S/S in the remediation technologies (Bates and Hills, 2015).

The stabilization/solidification approach can be applied both in situ and ex situ, and for remediating inorganic and organic contaminants in soil. The in situ approach is applied where the affected soil is not removed or excavated from its original place. In the case of ex situ, the soil is removed and taken to a dedicated stockpile area or facilities where the binding material is mixed with the pile.

Stabilization/solidification is suitable mostly for remediating soils that are contaminated with metallic compounds, high molecular weight polycyclic aromatic hydrocarbons, long-chain petroleum hydrocarbons or larger chlorinated compounds. This technology was developed in the 1950s and became popular in the remediation industry, probably due to its ability to achieve remediation goals with a minimum investment. However, its limitations, including the inability to remove or destroy contaminants from the soil have resulted in a loss of interest in this remediation process in some areas such as the USA and Europe, despite growing practice in some other countries like China (Shen et al., 2019).

Chemical stabilization

Chemical stabilization represents a cost effective and sustainable risk-based approach to the remediation of contaminated soil. The technique involves the incorporation of amendments into the soil to render the contaminant less available (less mobile and less bioavailable), and therefore it represents less risk. It is considered a sustainable technique as it does not involve offsite disposal of contaminated material and often makes use of relatively low-cost amendments. Industrial waste by-products such as red mud, steel slag, and waste materials high in phosphate are few of those amendment materials.

Chemical stabilization is applied largely for metal contamination, which cannot be treated by degradation, and is most suited to diffuse contamination of the surface soil. It is adaptable to site-specific conditions and can be applied in place on site. The application can be formulated based on treatability trials to achieve specific remediation targets, such as reducing the leachable concentration or reducing the bioavailable concentration below acceptable limit. It is most typically applied to diffuse surface contamination by incorporation of the amendment into the surface layer of the soil.

Stabilization of the contaminant is achieved by chemical reaction. The mechanism of stabilization depends on the nature of the amendment applied. Broadly, soil amendments for chemical stabilization may be classified into three categories: those that stabilize by increasing soil pH, those that result in the precipitation of specific less soluble minerals, and those that provide a surface for sorption of the contaminant in the soil.

Soil amendments that increase soil pH include lime and alkaline by products such as red mud and magnesium oxide. These stabilize metals in the soil by increased sorption to soil and precipitation which occurs at higher pH (pH 7–9 is typically optimal).

Amendments that target the precipitation of particular minerals include phosphates and sulfates, which aim to stabilize metals by the precipitation of low solubility metal phosphates and metal sulfates.

Materials that provide increased sorption include those with iron and aluminum oxides such as steel slag, red mud, fly ash and biochar. Chemical stabilization is achieved by specific and non-specific adsorption of metals to these surfaces.

Bioremediation

Bioremediation techniques involve the use of microorganisms to clean up contaminated soils, sediments, water, or air. This is not a new concept, as people have been utilizing this technology since the beginning of civilization, for example through composting. However, the term “bioremediation” is relatively recent. Bioremediation takes advantage of natural processes and relies on microorganisms such as bacteria, fungi, actinomycetes, and cyanobacteria, which can be found in nature or cultured in the laboratory.

The basic principle of bioremediation is that microorganisms can be harnessed to degrade or transform contaminants into nonhazardous or less hazardous chemicals (Fig. 3). These organisms obtain energy and nutrients for their growth and reproduction by oxidizing organic matter. To accomplish this, they require the presence of other chemicals that can be reduced, which are generally the oxidized inorganic compounds, such as oxygen, nitrate, iron(III), manganese(IV), sulfate, and carbon-dioxide (Palmisano and Hazen, 2003).

Under favorable conditions, microorganisms are able to gain energy or carbon from the breakdown of organic contaminants. Although most organic contaminants are biodegradable, metals and radionuclides are not. Despite this, microorganisms can interact with these non-degradable contaminants, altering their oxidation state through electron transfer, and thereby converting them from one chemical form to another.

The success of bioremediation depends not only on the types of contaminants but also on the characteristics of the site. When the remediation depends solely on indigenous microorganisms without any human intervention, it is referred to as intrinsic bioremediation or natural attenuation. On the other hand, when microbial activities are anthropogenically accelerated using microbial growth stimulating agents, such as nutrients or oxygen, this is known as engineered bioremediation or enhanced

Fig. 3 Microorganisms degrade organic contaminants and transform metals to forms that are less toxic in bioremediation.

bioremediation. Bioremediation can be conducted at the site where the contamination occurs, termed as in situ processes whereas off-site remediation (ex situ processes) involves removal of contaminated media to a treatment area (NRC, 1993).

Bioremediation is a viable alternative to traditional clean-up procedures, as it can potentially be more efficient, safer, and less expensive. There are several successful reports of bioremediation being applied to contaminated medium, however those exclusively in soil are limited. Among soil bioremediation examples, the remediation of fuel oil-contaminated soil at the Penrice Soda premises in Osborne, South Australia, stands out. It was carried out using a combination of biopile and enhanced bioremediation techniques, treating affected area of 3000 m³ with approximately 5000 KL of spill (ZWSA, 2013). Likewise, hydrocarbon remediation from Antarctic soil (Martínez Álvarez et al., 2017) or other examples given in the review by Stepanova et al. (2022) are worth noting.

Phytoremediation

Phytoremediation broadly refers to the use of plants for the remediation of contaminated soil. It is a green and low-cost remediation technology which has particular applicability to stabilize and remediate degraded environments such as those affected by mining and other industrial activities. It is best suited to shallow and widely dispersed contamination because its effectiveness relies on the root zone of the plants. Phytoremediation has been applied to the remediation of metals and organic contaminants, including PCBs, PAHs, BTEX compounds (benzene, toluene, ethylbenzene, and xylene), TCE, explosive residues, and pesticides.

There are two main applications of phytoremediation for metals: phytostabilization and phytoextraction. Phytostabilization refers to the stabilization of contaminants in the soil, while phytoextraction involves the extraction of contaminants from the soil. For organic contaminants, the phytoremediation process may involve immobilization, volatilization and mineralization of these compounds. Immobilization of contaminants occurs in the root environments, while certain compounds release to the air through plant roots, stems and leaves (volatilization), and mineralization is the conversion of toxic compound to non-toxic constituents (Tripathi et al., 2020).

The nature of the application defines how phytoremediation is designed and implemented. Plants differ in their ability to take up contaminants in soil, therefore for phytoextraction, plants known as “hyperaccumulators” are used to maximize uptake of the contaminant in soil into the above ground biomass of the plant. The plants may then be harvested and disposed of after sufficient uptake of the contaminant into the biomass of the plant. In the case of phytostabilization, where the plants will accumulate and stabilize the contaminant in the root zone of the plant, the effectiveness of different plant species will also vary.

The effectiveness of different species of plants depends on their physiology and the contaminant of concern because some contaminants are readily taken up by plants due to their chemical properties. The plant species used must also be resistant to toxicity from the contaminant, which would restrain its growth. Generation of sufficient biomass is also required for effective phytoremediation. Researchers have investigated which plants are most effective for different applications (D’Orazio et al., 2013; Jiménez et al., 2011; Gobelius et al., 2017). For example D’Orazio et al. (2013) reported that the greatest efficiency of pyrene removal from soil of 32% was achieved with *Medicago sativa* L. (Alfalfa). Jiménez et al. (2011) examined the accumulation of zinc, lead and copper from mine tailings by three plant species. They found *Diurichia viscosa* (L.) Greuter, 1973 to be a suitable “phytoextractor,” whereas *Euphorbia pithyusa* subsp. *cupanii* was considered a good “phytostabilizer” (Jiménez et al., 2011). Gobelius et al. (2017) assessed the capability of local plant species for the removal of PFAS from soil. Mixed stands of silver birch (*Betula pendula* Roth) and spruce (*Picea abies* (L.) H. Karst), and an understory of ground elder (*Aegopodium podogragaria* L.) had the potential to remove 1.4 g of PFAS per year per hectare.

The efficiency of phytoremediation may be restrained for several reasons due to soil properties, type of contaminants, plant physiology, and climatic conditions (temperature, rainfall and water availability). The phytoavailability of a contaminant relates to

its availability for plant uptake, which for metals relates to pH, solubility of the mineral form, and association with soil. For organic contaminants, it is related to sorption, degree of hydrophobicity, and a log octanol–water partition coefficient (Alkorta and Garbisu, 2001).

To meet the desired remediation goal, it may be necessary to use a chemical amendment to enhance the process. This can involve the use of a chelate or acid for phytoremediation of metals, or a surfactant in the case of organic contaminants. These substances promote the phytoavailability of the contaminant to increase their uptake by the plant.

In addition, recent research has focused on the role of endophytes, which are microorganisms found inside the internal tissues of plants, particularly in the context of organic contaminant degradation, promotion of plant growth, and increase of tolerance to contaminant toxicity (Feng et al., 2017). For example, a strain of *Enterobacter* sp. living in poplar (*Populus* sp.) plants could degrade TCE. This plant was harvested from a TCE contaminated soil site (Kang et al., 2012). Furthermore, Yao et al. (2022) reported that an endophytic bacterial community helped the black locust tree (*Robinia pseudoacacia* L.) in coping with metal stress while growing in the metal tailings of the Manao Mountain area in China.

Soil washing

Soil washing is a waste volume minimization treatment technology based on separation by physical and or chemical processes. It is a widely established treatment for the remediation of contamination in soils.

The technology enables the separation of contaminant from bulk soil, reduction of waste volume, easier handling of waste and reuse of the bulk soil fraction on the site as backfill. Contaminants sorbed onto fine soil particles are separated from bulk soil in an aqueous system, usually on the basis of particle size or density. The means of physical separation include:

- Mechanical (vibrating screens),
- Hydrodynamic (settling velocity, i.e., sedimentation),
- Gravity (density),
- Froth flotation (uses air or mechanical agitation to suspend particles or oil based on its hydrophobic properties),
- Magnetic separation (magnetic properties of materials and contaminants present in soil),
- Attrition scrubbing (agitation to remove contaminant from coarse particles).

The wash solution may use a basic leaching agent, surfactant, acid (pH adjustment), or chelating agent for enhanced removal of organics and metals (Fig. 4).

The target contaminant groups for soil washing are: metals, semivolatile organic compounds (SVOCs), selected volatile organic compounds (VOCs), and pesticides.

There are several considerations and limitations to the applicability and effectiveness of soil washing including:

- Additives must be of low toxicity and ideally be biodegradable,
- Contaminant removal efficiency for complex waste mixtures, high clay soils or very large concentrations,
- Large humic content in soil may require pre-treatment,
- Treatment of the washing solution is needed to recover contaminants from the waste stream,
- Recycling of the extraction solution may be required for cost effectiveness,
- The effect of the chemical washing solution may render soils unsuitable for some future use due to alteration of the soils' physical and chemical properties by the chemical washing process.

The remaining bulk soil is not totally contaminant-free. Therefore, for soil washing to be successful, the level of contamination must be below a site-specific action limit (e.g., based on risk assessment).

Fig. 4 Schematic diagram of soil washing treatment.

Fig. 5 Schematic diagram of soil flushing treatment.

Other considerations relate to the volume of contaminated soil to be treated (volume or coarse to fine material) and the capacity of the washing plant (tons hr^{-1}). Economies of scale should be applicable because of the large upfront costs of establishing the treatment succession on site; therefore the cost per cubic meter will be higher for a smaller site.

Soil flushing

Soil flushing is an in situ remediation technique that operates on a similar principle to chemical soil washing. However, in soil flushing the aqueous washing solution is introduced to the soil in place by injection or flooding. Contaminants in the soil are desorbed into the solution and extracted for treatment by extraction wells (Fig. 5).

Chemical reduction

Chemical reduction or in most cases the in situ chemical reduction (ISCR) technique is applied to convert a more toxic form of the contaminant into a less toxic form. Transformation of hexavalent chromium (Cr(VI)) or a dense non-aqueous phase liquid (DNAPL) compound trichloroethene (TCE) is one such case. In the case of Cr the tri-valent form is preferable due to its much lower toxicity and stability over the severely toxic Cr(VI) (Fan et al., 2016).

For this method of remediation, a chemical or material is used that has the electron transfer capacity to reduce the target compound or ions. Zero valent iron (ZVI) is a dominant type of material used. The particle size of ZVI varies, and so does its effectiveness. It varies in size from macro to extremely small particles, which is often referred to as nano zero valent iron (nZVI).

The mode of application of this reducing material depends on the site of the soil and the type of contaminant. It can be (i) applied directly or (ii) injected via a permeable reactive barrier (PRB) (Fig. 6). In the case of direct injection, the reactive material is presented as a slurry using water or nontoxic oil (e.g., vegetable oil) before being poured into several holes at the contaminated soil site. On the other hand, PRB is applied to treat the leachate flow of the contaminated site by creating a trench for the barrier where the reactive agent is placed. The outlet of the leachate is deemed to be less toxic once passed through this permeable trench (Fig. 6) (US-EPA, 2012c).

With the progress of this technology, ISCR material can be applied to achieve both reductive transformation of the target contaminant and also to enhance the bioremediation. The latter is achieved when the ISCR material like ZVI is incorporated with an organic additive, which is a microbial growth enhancer.

In situ oxidation

Like in situ chemical reduction (ISCR), the principle of in situ chemical oxidation (ISCO) is the conversion of the toxic form of a contaminant to it a less toxic form. For example, the reduction of TCE occurs in presence of permanganate following the chemical reaction of:

Oxidative breakdown of solvents, fuels or types of pesticides is the commonly targeted application. To that end, a range of reactive agents known as oxidants, including hydrogen peroxide, ozone, persulfate, and permanganate are applied. Depending on the target contaminant and source area, the type of oxidant is chosen and applied underground. The dissipation of these injections encounters

Fig. 6 The illustration of a permeable reactive barrier made of zero valent iron (ZVI) for the transformation of hexavalent chromium (US-EPA, 2012c).

Fig. 7 The illustration of in situ oxidation treatment system where the oxidants are typically injected underground by pumping them into wells (US-EPA, 2012c).

the target contaminant and acts as an electron receptor. This dissipation occurs most effectively when the agents are supplied below the surface through an installation with several holes at various depths from the surface to depth (Fig. 7) (US-EPA, 2012c).

Improvement of oxidants and the mode of application have been tested. The surfactant mediated oxidation process of polycyclic aromatic hydrocarbons (PAHs) and total petroleum hydrocarbons (TPHs) was deemed rapid and enhanced (Wang et al., 2013). Surfactants could increase the bioavailability of these petroleum compounds to be treated by oxidants.

The ISCR has a long history of remediation practice because of its fast performance and low-cost; also, it is performed underground leaving the surface soil arrangement intact. However, the application of ISCR is more appropriate for the remediation of groundwater than for the soil matrix.

Electrokinetic remediation

Electrokinetic remediation is an environmental technology that was designed specifically for removing pollutants from soil, sediments, and sludge, although it may also be used on any solid porous material. This technology uses a low-level direct current between electrodes placed across a section of contaminated media (Acar and Alshawabkeh, 1993).

Fig. 8 Ion transport mechanisms in electrokinetic remediation (Cameselle, 2014).

The electrokinetic remediation principle is similar to that of a battery. When the electrodes, cathodes and anodes are introduced into the soil matrix and a low-intensity current is applied, electroosmosis and ion migration take place (Fig. 8). The direction of aqueous phase contaminant movements depends on their charge. Anions and negatively charged organic molecules move toward the anode, whereas metals and positively charged organic compounds move toward the cathode. The contaminants can then be recovered or deposited at the electrode.

Electrokinetic remediation can be used to clean up soils contaminated with radionuclides, metals, and organic compounds. The application of this remediation technique to non-polar organic contaminants can be enhanced by the use of different surfactants.

The advantage of the electrokinetic remediation technique is its potential to be used both in situ and ex situ at a low cost. However, this is a time-consuming process and issues such as excessive heat generation in the vicinities of electrodes, and changes in soil pH could be a matter of concern. The timeframe required for electrokinetic remediation may be up to one or more years depending on the type of contaminants, size of treatment area, electrode spacing, the nature of treatment (biodegradation or chemical oxidation) and site-specific conditions such as aquifer conductivity and lithology (FRTR, 2020a).

Soil vapor extraction

Soil vapor extraction (SVE) is a conventional in situ remediation technique that is applied for the treatment of volatile and some semi-volatile organic contaminants (most commonly petroleum hydrocarbons and chlorinated VOCs) in the vadose zone of soil. The vapor extraction works by producing advective flow within the vadose zone by a pressure gradient created by the application of a vacuum to the extraction wells.

The technology comprises three processes, namely extraction, treatment, and venting.

There is a range of approaches available for each of the treatment processes. The treatment system typically comprises (CRC CARE, 2019b): extraction wells, a vacuum pump or blower, a low permeability surface cap, a vapor or liquid separator, and soil vapor treatment system. The soil vapor treatment system may take the form of granular activated carbon (filtration of contaminants from vapor), combustion and condensation. Venting is by exhaust to the atmosphere with a final scrubbing by the filtration system before release to the atmosphere (Fig. 9).

The effectiveness of the treatment may be affected by site conditions including lithology and heterogeneity of the subsurface, temperature, soil moisture, natural organic carbon content, and depth to groundwater (FRTR, 2020b). These factors affect the permeability of the air flow and therefore the efficiency of the process.

Contaminant properties also need to be considered when applying the treatment because SVE can be used only to remediate VOCs with a Henry's Law constant >0.01 or vapor pressure >0.5 mmHg (FRTR, 2020b). It can also be applied to non-aqueous phase liquids, dissolved organics, the sorbed phase and free soil vapor.

The costs of SVE tend to increase with the size and depth of contamination.

Thermal treatment

Thermal soil remediation removes organic contaminants from soil and other solid media by subjecting the material to temperatures high enough to volatilize the target contaminant. It is widely applied to organic contaminants, including persistent organic contaminants such as polychlorinated biphenyls, organochlorines and pesticides. A combined approach of injecting hot air stream

Fig. 9 Schematic diagram of soil vapor extraction in combination with the purging of air to the sub-surface.

and vapor extraction is often referred to as “Thermally enhanced SVE” (FRTR, 2020c). Remediation may be achieved over a relatively short timescale (weeks to months). It works by separating the contaminant from the soil by heating it to boiling point and transforming the contaminant to the gas phase. The gas then passes through an off-gas treatment system to destroy or absorb/adsorb off-gases generated by the thermal treatment.

The thermal treatment may have a range of configurations (Vidonish et al., 2016):

- Fired thermal desorption (soil fed through a rotary kiln with a flame),
- Enhanced thermal conduction (heating rods pipe hot air through the soil mound),
- In situ thermal (several methods, including hot air injection, steam injection, electromagnetic heating, electrical resistance heating, vitrification and electrothermal dynamic stripping), and
- Indirectly heated thermal desorption (similar to fired thermal, but the heat source is external to the desorption chamber).

For thermal treatment, soils of lower permeability (silty and clay) are less expensive to remediate as they require less gas flow. Similar to other treatment technologies, the depth and thickness of the contamination zone is associated with higher costs of application of the technology.

Conclusions

Several technologies are available for the remediation of contaminated soil. Choosing the appropriate remediation technology depends on the type of contaminants and the site conditions. In addition, sustainability needs to be considered, such as cost effectiveness and potential environmental impacts and benefits. The configuration of treatment technologies should be tailored to site-specific application to optimize the remediation of a given site.

Abstract

Soils change naturally as the parent material and minerals are progressively weathered, and in response to the growth of plants, animals and microorganisms across landscapes. In the past century, human-induced changes to the global climate and land use have put soils at risk of degradation. Erosion of fertile topsoil, loss of soil organic matter, element imbalances resulting from salinization, trace metal pollution and excessive fertilization, are some of the most damaging soil changes that we must resolve to sustain our soils, a vital natural resource. This chapter explains the reasons for these changes in soil, and the human activities that are likely to accelerate or slow this rate of change. Possible scenarios to improve the soil's resilience to change and prevent its depletion are presented.

Key points

- Soil change is associated with geological processes and land use conversion for agriculture.
- Soil erosion and loss of soil organic matter from fragile landscapes are associated with food insecurity, water shortages and ecological damage.
- Loss of sediments and soil organic matter can be prevented by revegetating and stabilizing vulnerable areas with built control structures, and adopting conservation agricultural practices.
- Element balances in soil are affected by improper fertilizer use and irrigation, as well as contaminants deposited from atmospheric pollution.
- Judicious fertilizer and water use are needed to control the amounts of essential and non-essential elements that affect biological processes and abiotic reactions in soil.
- Local, regional and national programs are needed to measure and monitor soil change.

Introduction

The United Nations declared 2021–2030 as the Decade on Ecological Restoration, which is a call for action to prevent, halt and reverse ecosystem degradation worldwide. We must rebuild ecosystems to achieve the sustainable development goals of food security, climate change mitigation, water and biodiversity conservation and eradication of poverty. This requires us to address issues related to land degradation, which affects an estimated 25% of the land surface and is estimated to reach 95% of the global land area by 2050. Land degradation is the change in the biophysical environment that causes deterioration or loss of productive soils. Such a change in the soil condition can limit the growth of desirable vegetation, which we use as food, fuel, fiber and depend upon for oxygen, regulation of hydrologic processes and other essential ecological services. Soil change can also diminish its biodiversity, capacity for biogeochemical cycling and ability to attenuate contaminants in the environment.

Soil change is largely a human-induced phenomenon that has dire consequences for the world's population. The erosion of about 24 billion tons of fertile soil each year impacts 3.2 billion people, approximately 40% of the world's population. About 33% of soils worldwide have lost soil organic matter due to historical expansion of agriculture and pastoralism, which converted many native ecosystems (e.g., peatlands, forests, grasslands) for arable land use. Element imbalance due to soil salinization affects more than 830 million hectares of cultivated land worldwide and is expected to impact about 50% of arable land by 2050. These alarming trends must be stopped and reversed to ensure that soils continue to support vital ecosystem functions, creating a stable or improved land resource that can provide the necessary habitat and products that are needed to fulfil the Earth's biological needs.

This chapter explains the root causes of soil change due to human activities related to the conversion of natural ecosystems for agricultural use in the context of global climate change. Case studies are presented to explain the consequences of soil change,

as well as the time needed for regional-scale restoration processes to be effective. These examples offer some concrete solutions to the problems that result from soil change, while explaining the necessity of stakeholder involvement, policies and economic investments to control soil change.

Soil change due to erosion

Erosion is part of the natural weathering process that leads to the physical and chemical degradation of rocks, sedimentary materials and minerals, moving smaller particles and dissolved substances from one location to another in the landscape. Soil erosion refers to the physical movement of soil particles and associated organic matter, generally from the soil surface, following abrasion by mechanical forces. Wind, water, ice and machinery exert sufficient force to dislodge particles and move them to a new location, with the help of entropy and gravitational forces. Natural soil erosion, also referred to as geological erosion, occurs at a relatively slow rate of <0.2 mm per year, which is equivalent to the annual removal of approximately $1 \text{ Mg topsoil ha}^{-1}$ (Montgomery, 2007). In the absence of human activities, geological erosion is responsible for gradually moving soil from weathered landscapes and depositing particles in new locations, over hundreds to thousands of years. Geological erosion adds dust and water-borne sediments to the soil profile developed through weathering, at a rate of $0.04\text{--}0.08$ mm per year; this rate of soil formation is close to the global average rate of erosion of 0.05 mm per year under native vegetation (Montgomery, 2007). Thus, there is an equilibrium between soil formation and erosion in ecosystems that are free from human disturbance.

Soil change due to erosion: The case of the Chinese Loess Plateau

Geological erosion creates landforms of major importance, such as the Chinese Loess Plateau, which covers $640,000 \text{ km}^2$ in Gansu, Shaanxi and Shanxi provinces. Home to more than 100 million people, the Loess Plateau is the world's largest formation of yellow wind-blown sediment, which develops into a unique soil type called loess. Soil on the Loess Plateau originates from mountains (the Gobi Altai Mountains, the Hangayn Mountains and the Qilian Mountains) in south-central Mongolia and northwestern China. Physical weathering of the rocks in these mountains, aided by freeze-thaw and flowing water, generates small-sized grains that gradually move into the Gobi Desert and surrounding sand deserts. The prevailing winds, together with monsoons and dust storms, transport silt-sized particles from the Gobi and other deserts for hundreds of kilometers. The gradual decline of wind energy upon arrival at the Loess Plateau means that larger, heavier particles are deposited in the northwest region and finer clay particles are found in the southeast of the area. Aeolian sediments are deposited at a rate of about 0.1 mm per year, so it takes around 10,000 years to produce 1 m of loess soil. The wind-borne dust is gradually transformed into a grey-yellow palaeosol through three soil-forming processes: (1) primary calcite particles within the dust are dissolved in rainwater and leached, leading to secondary CaCO_3 deposition on silt and clay particles, (2) organic matter accumulates due to the growth and turnover of organic substances from plants, microorganisms and animals, and (3) some minerals in the loess are gradually weathered into finer clay particles and form complexes with organic substances and iron oxides (Zhao et al., 2017).

Agriculture speeds up soil erosion, particularly on hilly, sloping landscapes in the Chinese Loess Plateau. Rates of soil erosion are nearly two orders of magnitude greater in conventional agriculture, with a global average of 3.9 mm soil eroded per year, compared to under native vegetation (Montgomery, 2007). Reports of soil erosion on the Loess Plateau date back more than 2000 years, when farming began in the region. Ongoing soil loss changed the geomorphology, such that 70% of the Loess Plateau became dominated by hills and gullies as the loess gradually washed into tributaries of the Yellow River. Excessive sediment loading in the Yellow River is linked to more than 1500 floods between 602 BC and AD 1947, with at least 26 major and 9 severe shifts in the channel of the Yellow River during this time (Douglas, 1989). Each flood inundated a large area of the South China Plain, depositing huge quantities of silt and sand across the delta, displacing villagers and negatively affecting river commerce. By the 1980s, the overuse and overgrazing of highly-erodible loess produced some of the highest erosion rates ever recorded. Maximum annual suspended sediment loads of 5000 Mg km^{-2} to more than $35,000 \text{ Mg km}^{-2}$ in tributaries of the Yellow River (Table 1) led some observers to remark that the loess highlands below Hekouzhou were the most severely eroded land on Earth (Douglas, 1989). Around this time, the Yellow River reached its capacity for sediment loading, meaning that the river was carrying the maximum sediment it could

Table 1 Maximum annual suspended sediment loads recorded in tributaries draining the Chinese Loess Plateau from 1956 to 1980.

River tributary	Station	Drainage area (km^2)	Maximum annual suspended sediment load (Mg km^{-2})
Yellow	Longmen	497,559	4944
Weihe	Huaxian	106,498	9953
Huangfu	Huangfu	3199	53,454
Beiluo	Zhuangtuo	25,154	8587
Kuye	Wenchuan	8645	35,049
Wuding	Chuankou	30,217	14,561

transport. Centuries of sediment deposition have created an elevated river that rises as much as 10 m above the level of the surrounding land. Millions of inhabitants in the Yellow River Delta live with the threat of disastrous flooding, which endangers human life and destroys property, because the volume of fast-flowing, sediment-laden water in the Yellow River has the capacity to breach dams, dikes and levee banks. Government officials and their advisors agree that perpetual control of soil erosion on the Loess Plateau is the only way to ensure public safety and prevent further degradation of the Yellow River.

Stabilizing the loess is the most direct way to reduce sediment loading in the Yellow River. This begins with terracing, a land-forming practice that cuts a sloped land surface into a series of flat platforms that resemble steps. Terracing was a traditional practice in this area that was improved by better design and construction after the 1950s. Less than 1% of the Loess Plateau was terraced in the mid-1950s, and this increased to about 15% of the land area by 2018 (Ji et al., 2021). Terracing prevents soil loss because the outer edge of the terrace has an elevated earth embankment, at least 20-cm high, that prevents slope erosion by retaining sediments, water and dissolved substances. Terraced fields retain more water, as much as 100–200 mm after heavy rainfall events, without appreciable erosion, and always have higher soil moisture than sloped land (Liu et al., 2011). Greater soil moisture supports the growth of deep, extensive plant roots, resulting in more above-ground biomass and larger crop yields. In Zhuanglang County, the average grain yield was 27% greater in 3-year old terraces and 53% more in 7-year old terraces than on hilly fields with $\geq 10^\circ$ slope (Table 2; Liu et al., 2011). Since roots are generally not harvested, an intact root system with long, dense root hairs and lateral branching roots can effectively adhere to soil in the root:soil contact surface area, thereby preventing erosion.

Although terraces can retain about 10 times more sediment than cultivated slopes, landowners must manage their terraced fields carefully to avoid soil loss through wind and water erosion. Low-disturbance tillage methods such as minimum-tillage, no-tillage and contour plowing, which turns the soil across the slope rather than up-down the slope, are preferred to conventional plowing methods. These low-disturbance techniques can reduce the volume of surface runoff by more than 50% and prevent up to 75% of sediment loss from terraced fields (Wei et al., 2014). Including perennial crops in the rotation, intercropping to increase the vegetative cover in row-cropped systems, applying green manure, retaining straw as a mulch after crop harvest, and planting drought-tolerant varieties that produce high yields with less water are also promoted on the Loess Plateau (Wei et al., 2014). These agricultural practices are expected to prevent erosion while simultaneously increasing water retention and improving soil fertility, which will sustain crop yields and contribute to the economic prosperity of landowners in this region.

Erosion control in the hilly and gully regions of the Loess Plateau requires construction of water-retaining structures such as water caves, water banks and check dams that can trap surface runoff and sediments. Check dams built in the gullies of sloping lands are particularly effective for retaining sediments (Fig. 1). They consist of an earth dam, which may be built on top of stone or wood,

Table 2 Winter wheat production in dryland terraced fields, relative to unimproved hillslopes, during the 1990s in Zhuanglang County, eastern Gansu Province in the Chinese Loess Plateau.

Age of terraced field	Average yield (Mg ha^{-1})	Yield gain relative to unimproved hillslope (Mg ha^{-1})	Yield gain relative to unimproved hillslope (%)
First year of establishment	2.9	0.1	4
After 3 years of construction	3.6	0.8	27
After 5 years of construction	3.8	1.0	35
After 7 years of construction	4.3	1.5	53
Unimproved land with $\geq 10^\circ$ hillslope	2.8

Fig. 1 Check dam in the Wuding River watershed of the Chinese Loess Plateau, showing the extent of sediment deposition (a), and water retention (b) behind the check dam. From Shi P, Zhang Y, Ren ZP, Yu Y, Li P and Gong JF (2019) Land-use changes and check dams reducing runoff and sediment yield on the Loess Plateau of China. *Science of the Total Environment* **664**: 984–994. doi: 10.1016/j.scitotenv.2019.01.430.

and a culvert that discharges flood water, generally without a spillway. The primary function of a check dam is to prevent gully incision by the network of headward-growing tributaries (first order streams of the Yellow River). Check dams can reduce the erosion energy to nearly zero in areas where gully and gravity erosion were the main cause of stream incision and bank failure that loaded sediments into the Yellow River (Shi et al., 2020; Wang et al., 2021). Sediments accumulate behind the earth dam, where they remain even if the dam fails, and effectively reduce the runoff velocity and erosion energy for many years. An estimated 110,000 check dams were constructed in thousands of gullies on the Loess Plateau since the 1960s. Each one has capacity for 0.01–5 million m³ of sediments, depending on the geomorphology of the gully, which could be up to 50-m deep, leading to a total retention of about 4 billion m³ of sediments by 2020 (Wang et al., 2021).

Check dams in gullies will prevent sediments from entering the Yellow River. A study in the Loess Mesa Ravine Region demonstrated that more 90% of the surface runoff and sediments from hillslopes were retained in a single check dam, although it only occupied 2.3% of the total conserved land (Fig. 2; Xu et al., 2012). The check dam was far more effective at controlling soil

Fig. 2 Check dam farmland retained more than 90% of the (a) water and (b) eroded soil, compared to other conservation practice (terracing, tree-planting and grassland restoration) in the Nanxiaohogou Catchment, a 36.3 km² watershed in the Loess Mesa Ravine Region near Qingyang, eastern Gansu Province in the Chinese Loess Plateau. Adapted from Xu XZ, Li MJ, Liu B, Kuang SF and Xu SG (2012) Quantifying the effects of conservation practices on soil, water, and nutrients in the Loess Mesa Ravine Region of the Loess Plateau, China. *Environmental Management* 49: 1092–1101. doi: 10.1007/s00267-012-9835-4.

erosion than terracing and forest or grassland revegetation in this region. Sediments collected in check dams created more than 18,100 ha of new farmland by 1999, and this increased to 69,000 ha by 2007 (Shi et al., 2020). Furthermore, the farmland with check dams is 8–10 times more productive than the surrounding hillslopes, and it can produce about twice as much grain yield per unit area as terraced fields (Shi et al., 2020). Despite its small land area, check dam farmland could generate about 15% of the annual grain production on the Loess Plateau, which contributes to food security and economic prosperity in this region.

Traditionally, large tracts of the Chinese Loess Plateau were covered with perennial vegetation including forests, shrublands and grassland. As the human population of the Loess Plateau increased, from 8 million about 2000 years ago to 36 million in 1949 and more than 81 million in 1985, much of the native vegetation was removed as land was converted for agricultural use and steeper slopes were cultivated. Forests covered 50% of the Loess Plateau around 2000 years ago, but were only 6% of the land use by 1949 (Ji et al., 2021). The rapid expansion of cultivated lands, coupled with overgrazing by goats and excessive gathering of fuelwood, severely depleted vegetation in the uncultivated areas of the loess highlands, leaving the steep slopes vulnerable to severe gully and slope erosion by the 1970s and 1980s. Tree planting programs began in the mid-1950s with a more intensive, large-scale afforestation scheme starting in the late 1970s to revegetate the bare hills and minimize soil erosion. However, only about 25% of trees planted during 1950–1980 survived because the chronic water shortage in this area could not support species like the locust tree (*Robinia pseudoacacia* L.), Chinese pine (*Pinus tabulaeformis* Carr.) and sea buckthorn (*Hippophae rhamnoides* L.). Furthermore, trees grow relatively slowly in the semi-arid climate of the north and north-central Loess Plateau. It can take many years before trees produce sufficient leaf surface area to intercept rainfall, reducing its erosive force on the soil surface. Tree roots also protect soil from erosion, since the soil mass attached to tree roots is 13 times greater than the weight of the tree root system (Tanikawa et al., 2021), but it requires time for the tree roots to grow and stabilize the soil mass. Better tree growth occurs on slopes when a check dam is constructed, since the earth dam will prevent trees and shrubs from being destroyed by gully erosion. After installing a check dam and then planting trees, the vegetation cover on two hilly watersheds of the Loess Plateau increased from 1% to 5% to between 40% and 50% from 1955 to 1990 (Wang et al., 2021). The government provides financial compensation for tree planting, which resulted in the reestablishment of forest on about 11–15% of the land in the Loess Plateau from 1986 to 2018 (Fig. 3; Ji et al., 2021).

It is easier to establish perennial grasses and legumes than woody plants in the semi-arid regions of the Loess Plateau. Restored grasslands increased at a rate of about 6700 km² per year from 1986 to 2018, reaching an estimated 43% of the land area by 2018 (Fig. 3; Ji et al., 2021). Grasslands are well-adapted to grow in this area and more effective than other types of vegetation for retaining water and reducing sediment loss. Grasslands restored through natural revegetation are dominated by native plants from the genus *Artemisia*, *Agriophyllum squarrosum* and *Lespedeza davurica*, as well as the grasses *Agropyron cristatum*, *Bothriochloa ischaemum*, *Cleistogenes songorica* and *Stipa* species. Passive grassland restoration occurs when sloping farmland is taken out of cultivation, which improves the soil's resistance to erosion within 15–20 years. For example, soil resistance to slope erosion peaked after 18 years, and this was associated with grassland species that produced more root mass, especially roots that were 0.5–1 mm long, near the soil surface (Guo et al., 2020). At other locations, vulnerable slopes were reseeded with perennial legumes like alfalfa (*Medicago sativa* L.), after excluding grazing animals. However, the large water demand of alfalfa and other introduced plants means that they cannot be sustained in the longer term. The current strategy is to reduce the populations of water-demanding plants by broadcasting seeds of native vegetation and water-saving plants. This should maintain the vegetative cover whilst conserving the scarce soil water resources in the region.

Restoration of the Loess Plateau requires systematic, government-sponsored programs to coordinate land use activities in the area. For example, the 'Grain-for-Green' program that began in 1999 aimed to stop the cultivation of unstable loess highlands, the hilly and plateau-gully lands. The goal of this program was to replant or allow natural revegetation on hilly lands with >25° slope, as well as on degraded cropland and barren land. By the end of 2012, the Grain-for-Green program was credited with converting 9.1 million ha of cropland to forest, and an additional 0.64 million ha of cropland was revegetated as grassland (Fig. 4; Wu et al., 2020). This program is considered a model to improve land use in other parts of China, and worldwide. However, the success of this program required a major shift in government policy. One of the most important policy changes was declaration of the 'household responsibility system', which allowed decades-long leases of the land. Secure land rights gave farmers and herders more incentive to care for the land because a family could expect future benefits from their investment in land improvement. Another key action was to implement a payment scheme to compensate farmers for converting sloping cropland into woodland or grassland. Initially, the Grain-for-Green program promoted afforestation of ecological trees and shrubs, but by 2012 the policy changed to give greater financial compensation to landowners that planted edible tree crops. Consequently, orchards of fruit and nut trees have gradually replaced annual crops and perennial species on the steeper slopes. Today, orchards cover about 15% of the Loess Plateau (Ji et al., 2021), and farmers on the Loess Plateau are the leading producers of apples in China because fruit production is more profitable than grain production in this region.

Deforestation, overgrazing and intensive agriculture were the leading causes of the severe soil degradation and erosion across the Chinese Loess Plateau. The restoration efforts have greatly reduced soil loss from this area, but they have cost millions of dollars. For example, the World Bank and its partners in China invested more than US\$500 million in the Grain-for-Green program. Financial compensation remains an important way to stabilize rural incomes and encourage millions of people to maintain the erosion control structures across this fragile landscape. This example, which is the world's largest erosion control program, demonstrates that humans can reverse negative soil changes due to erosion. While the Grain-for-Green program appears to have been successful for restoring soil productivity, there remain challenges ahead. More water is needed to maintain the current land use. Temperature is rising and rainfall is declining due to global climate change. These climatic changes led to an unexpected ecohydrological outcome, namely a reduction of –0.46 mm per year in streamflow from watersheds across the Loess Plateau (Chen et al., 2020). Therefore, we must continually consider the multiple human-ecological dimensions of soil restoration efforts in our quest to rebuild sustainable soils on the Chinese Loess Plateau.

Soil change due to loss of organic matter

Soil organic matter (SOM) is the litter and debris in soil that comes from plants, animals and microorganisms (Fig. 5). It consists of larger materials that are readily identified as having a biological origin, such as plant residues (leaves, stems, branches and roots) and animal dung, as well as microscopic organic substances that associate with soil minerals in organo-mineral complexes. Organic compounds in organo-mineral complexes are either the decomposition products of plant and animal residues, or secretions and cellular debris produced by plant roots, soil animals and soil microorganisms.

Organic matter for soil stability

The SOM content in grassland and forest ecosystems is maintained in a steady-state by the regular inputs of carbon derived from plant photosynthates, and supplemented by microbially-mediated nitrogen and sulfur fixation, as well as phosphorus and sulfur weathering from parent material. The steady-state is affected somewhat by geological erosion, which moves SOM across the landscape and transfers sediments to downstream environments. However, in most uncultivated ecosystems, the accrual of new organic carbon is equivalent to or greater than the carbon lost during decomposition (e.g., as carbon dioxide respired by soil

Fig. 4 (a) The boundary of the Chinese Loess Plateau and provinces in this region, with (b) a typical landscape in 1984 and (c) after 12 years of land management under the Grain to Green Program. From Wu XT, Wei YP, Fu BJ, Wang S, Zhao Y and Moran EF (2020) Evolution and effects of the social-ecological system over a millennium in China's Loess Plateau. *Science Advances* 6: eabc0276. doi: 10.1126/sciadv.abc0276.

organisms and dissolved organic carbon that leaches through the soil profile). Organic matter agglomerates with clay and silt minerals to form an aggregate structure. The connected network of macropores between aggregates and micropores within aggregates allow water and dissolved solutes to percolate through the soil matrix. The pore network facilitates air exchange with the atmosphere, creates channels for plant root growth, provides a microhabitat for microbial life and allows soil organisms to move through soil layers, including the surface litter. When SOM is lost following the conversion of forests and grasslands for agriculture, this can drastically affect the soil stability.

Soil change from organic matter loss after deforestation: The case of New Zealand pastures

The islands of New Zealand in the southwest Pacific Ocean were the last large habitable landmass to be settled by humans—first by Māori people around 1300 and later by European settlers in the 1800s. Geographically, the country is dominated by mountains (>1000 m, about 20% of the land surface) and hilly landscapes with steep non-arable hills below 1000 m representing ~40% of the land surface. At least 75% of New Zealand's land surface was forested until about 1200 years ago, but this changed after

Fig. 5 Decomposing litter and organic debris becomes soil organic matter (SOM) in the dark brown topsoil above the mineral subsoil of a Brazilian Oxisol. The SOM contains an abundance of nutrients and stores water for growing plants. The SOM is a component of soil aggregates, which stabilize the soil structure, reducing compaction, erosion and surface crusting, while increasing water infiltration into the soil. colonization. Hand-felling of forest trees has occurred for centuries, but the rate of deforestation reached a peak around the beginning of the 20th century. After trees were removed, the area was burned and then planted with grass for pastoral use or cropped. Currently, cultivated and pastoral lands represent more than 50% of the total land area (about 14 million hectares) in New Zealand.

In the Waipaoa Basin (North Island, New Zealand), deforestation has significantly modified the landscape in the past 200 years. The European settlers to this area converted ~90% of the native podocarp forest to pasture using repeated slash-and-burn techniques starting in the 1870s. Recently burned land was seeded with ryegrass (*Lolium perenne* L.), clover (*Trifolium repens* L.) and cocksfoot (*Dactylis glomerata* L.) to feed livestock, and systematically overgrazed with cattle and sheep to prevent native vegetation from regrowing. Initially, the land was quite prosperous, supporting 10–12 sheep per hectare. By 1910 there was an increase in soil erosion and declining soil fertility, which required farmers to reduce the sheep stocking density by about 50%. By 1920, the immense soil erosion problems were acknowledged in a New Zealand Geological Survey Bulletin, which warned of the impending danger from landslides in the area (Cervovski-Darriau and Roering, 2016). It took 40–50 years before soil degradation was evident because deforestation practices in Waipaoa Basin removed timber and above-ground components (stems, branches, leaves) but left roots undisturbed. Eventually, the roots of felled trees decayed and SOM levels plummeted. Grazing animals compacted the soil surface, reducing water infiltration into the soil profile. Furthermore, the soil parent material in this region is weakly lithologic sandstone and mudstone that has a natural vulnerability to landslides when rapidly rewetted after dry periods (Fig. 6). Episodic heavy rainfall delivers large volumes of water that flow across the denuded, geologically unstable hilly landscape, resulting in severe soil erosion, gullying and landslides. Consequently, the annual suspended sediment load in the Waipaoa River increased more than six times after European settlement of the region, and was one of the highest sediment yields in the world that is directly attributed to human modification of the landscape (Kettner et al., 2007) (Fig. 7).

In response, watershed managers in the Poverty Bay Catchment Board developed a major flood control and soil conservation scheme in the 1950s that led to dedicated reforestation programs in the upstream and headwater regions of the Waipaoa Basin. This reduced catchment erosion rates of nearly 30 mm per year in the 1950s and 1960s to less than 10 mm per year by 2010 (Cervovski-Darriau and Roering, 2016). Reforestation is an effective strategy for land restoration, but it takes time for trees to establish and stabilize the soil mass, particularly in the landslide-prone areas of the hill slopes where ongoing soil movement often topples or buries saplings before they have a chance to grow. The success of reforestation programs also requires agencies to suitable incentives that encourage local communities to plant trees on their land-holdings. One effective policy has been to exclude grazing animals, especially cattle, from the unstable slopes, which will allow native trees to regrow. For example, the natural regeneration of 10-year-old shrubland of endemic manuka (*Leptospermum scoparium* J.R. Forst & G. Forst) and kanuka (*Kunzea ericoides* (A. Rich.) Joy Thomps. Var. *ericoides*) sustained 65% less damage from landslides than pasture, and there was 90% less soil loss under a 20-year-old stand than under pasture (Bergin et al., 1995).

Reforestation, whether by deliberate tree-planting or natural revegetation, can effectively control soil erosion. The amount of soil stabilization depends upon the stand density of planted or natural regeneration forests, as well as root traits of woody plants and the magnitude of the root–soil adhesion (Fig. 8). An extra benefit of reforestation is the ability of trees to sequester carbon.

Fig. 6 Photographs of common sediment production processes in the Waipaoa River watershed, New Zealand. (a) Deep-seated landslides often deliver sediment and other terrigenous materials to channels. (b) Many gullies, like the Tarndale Slip, developed after European settlement, and expanded in size as water dislodged sediments from the land surface and carried them downstream. (c) Shallow landslides like these triggered by the 1988 Cyclone Bola mobilize the soil mantle. (d) Slow-moving earthflows impart a fluid-like appearance to hillslopes and generate rapid slope relaxation in response to surface water movement. From Kuehl SA, Alexander CR, Blair NE, Harris CK, Marsaglia KM, Ogston AS, Orpin AR, Roering JJ, Bever AJ, Bilderback EL, Carter L, Cerovski-Darriau C, Childress LB, Corbett DR, Hale RP, Leithold EL, Litchfield N, Moriarty JM, Page MJ, Pierce LER, Upton P and Walsh JP (2016) A source-to-sink perspective of the Waipaoa River margin. *Earth-Science Reviews* 153: 301–334. doi: 10.1016/j.earscirev.2015.10.001.

At least 1.45 million ha of marginal pastoral land has the potential for natural regeneration, which represents a possible carbon gain of about 2.9 million Mg C yr⁻¹ or nearly one-third of the annual energy-related carbon emissions in New Zealand (Trotter et al., 2005). In 2018, the New Zealand government announced an ambitious strategy to plant one billion trees by 2028 to capture carbon dioxide and reach its Paris Agreement targets for 2030 and 2050. Forested lands will be eligible for carbon sequestration payments from New Zealand's Emission Trading Scheme. Conversion of permanent pastures to forests should be a positive step for soil conservation and water protection, and is expected to rebuild the SOM content across hilly landscapes.

Organic matter for soil fertility

Soil organic matter is a well-known source of soil fertility because it contains essential plant nutrients in organic forms—nitrogen (N), phosphorus (P) and sulfur (S) that are hydrolyzed into soluble ions—and it has charged surfaces that retain cations, such as potassium (K⁺), magnesium (Mg²⁺), calcium (Ca²⁺), and anionic forms of boron (B⁻) and molybdate (Mo⁻) that are required for plant nutrition. Ions released or exchanged from SOM are essential for the nutrition of soil microorganisms, plants and animals. Loss of SOM is often associated with low soil fertility, for several reasons. Soils with low organic matter content have smaller reserves of the essential macro- and micro-nutrients. Soil organic matter acts like a sponge for water, and water is often the most limiting factor for plant growth and other soil biological processes. Furthermore, soil aggregate structure is diminished following the loss of SOM, which interferes with biological processes and impedes water and gas exchange between the soil and its surroundings (e.g., the atmosphere and the vadose zone). Intensive cultivation is well-known to deplete the SOM, leading to an overall loss of soil fertility.

Soil change due to organic matter loss following cultivation: The Great Plains prairie grasslands

Prairie grasslands covered more than 1.7 million km² in the Great Plains of central North America before the arrival of European settlers. The underlying black, dark brown and brown soils (Mollisols) contained appreciable quantities of organic matter that accumulated from thousands of years of biomass production in the grassland. A native tallgrass prairie can produce from 5 Mg to 10 Mg shoot biomass ha⁻¹ per year, with an additional 8–15 Mg root biomass ha⁻¹, adding an estimated 4–5 Mg C ha⁻¹ in plant residues to grassland soils each year (Huggins et al., 1998). This is supplemented by decay-resistant charcoal left after grasslands burned through natural fires (e.g., started by lightning strikes) and cultural burning by Native Americans as part of their hunting, animal husbandry and plant cultivation practices. Consequently, soils in the Great Plains have an estimated soil C storage of about 70–130 Mg C ha⁻¹ in the topsoil to 30-cm depth (DeLuca and Zabinski, 2011).

Fig. 7 Widespread land use changes following European deforestation of the Waipaoa Basin (North Island, New Zealand) in the 1870s, for establishing pasture grasses for sheep and other grazing animals, have caused a profound change in the Waipaoa River system. Prior to the 1870s, the annual mass of eroded soil and other terrestrial material (expressed as the terrigenous flux) was around 0.2 g cm^{-2} . Initial land disturbance increased the suspended sediment discharge in the Waipaoa River system by 350%, and this reached 660% once the headwaters were deforested in the 1920s. From Kettner AJ, Gomez B and Syvitski JPM (2007) Modeling suspended sediment discharge from the Waipaoa River system, New Zealand: The last 3000 years. *Water Resources Research* **43**: W07411. doi: 10.1029/2006WR005570.

Government policies in the late 1800s and early 1900s allowed European settlers to establish farms across the region, and was supported by U.S. and Canadian legislation such as the Land Act, the Homestead Act, the Dominion Lands Act and the Swamp Land Act. Settlers cultivated about 1.4 million ha per year of tallgrass prairies in the mid-1800s, with an additional 500,000 ha per year of mixed and short grass prairies in the early 1900s. By the mid-1930s, more than 90% of the original prairie had been converted to cultivated crops, primarily maize (*Zea mays* L.), wheat (*Triticum aestivum* L.), and oats (*Avena sativa* L. 1753). By 2020, less than 5% of the original, undisturbed tallgrass and mixed grass prairies remained in the northeastern Great Plains.

The initial conversion of prairie grassland to agriculture was accompanied by a significant loss of SOM. An estimated 45–70% of the soil organic carbon in the native prairie was lost in the first 25 years of cultivation in Illinois and Missouri (Huggins et al., 1998). The main reason for this is that annual cereal crops produced relatively little root biomass compared to native prairie, and most of the above-ground biomass is harvested. Grain accounts for about 50% of the above-ground biomass of annual cereal crops and is removed from the field at harvest. Often the straw is also harvested for animal bedding, fuel and other purposes. Roots remain in the field, but add a modest amount of organic matter to the soil because annual grain crops produce only about 20% of the plant biomass. This contrasts with native grasses whose roots form 50–70% of the plant biomass and introduced grasses with a root system weighing 35–50% of the plant biomass (Table 3; Wilsey and Polley, 2006). This means that a grain crop producing 10 Mg above-ground biomass ha^{-1} grows 2 Mg root biomass ha^{-1} each year, whereas a tallgrass prairie with 10 Mg above-ground biomass ha^{-1} has $5\text{--}7 \text{ Mg}$ root biomass ha^{-1} . Furthermore, annual cereal crops are photosynthetically active and fix carbon dioxide from the atmosphere for a relatively short growth period, around 100–150 days, whereas a perennial grassland photosynthesizes throughout

Table 3 Root mass fraction, expressed as the fraction of root mass (shallow and deep roots) in the total plant biomass (roots and shoots) of selected crop and grass species grown in the Great Plains.

<i>Plant species</i>	<i>Root mass fraction</i>
Crops	
Corn (<i>Zea mays</i>)	0.18
Soybean (<i>Glycine max</i>)	0.15
Oats (<i>Avena sativa</i>)	0.40
Barley (<i>Hordeum vulgare</i>)	0.50
Wheat (<i>Triticum</i> spp.)	0.20
Sunflower (<i>Helianthus</i> spp.)	0.06
Permanent hayfield	0.87
Introduced C ₄ grasses	
Yellow bluestem (<i>Bothriochloa ischaemum</i>)	0.20
Kleingrass (<i>Panicum coloratum</i>)	0.23
Dallisgrass (<i>Paspalum dilatatum</i>)	0.26
Native C ₄ grasses	
<i>Schizachyrium scoparium</i>	0.50
<i>Sorghastrum nutans</i>	0.39
<i>Bouteloua curtipendula</i>	0.34
<i>Bothriochloa laguroides</i>	0.25
<i>Sporobolus asper</i>	0.57
Native forbs	
<i>Echinacea purpurea</i>	0.48
<i>Ratibida columnifera</i>	0.19
<i>Salvia azurea</i>	0.49

Adapted from Wilsey BJ and Polley HW (2006) Aboveground productivity and root-shoot allocation differ between native and introduced grass species. *Oecologia* **150**: 300–309. doi: 10.1007/s00442-006-0515-z.

the frost-free period. Consequently, the annual carbon input from plant residues decreased from about 5 Mg C ha⁻¹ under native prairie to less than 1 Mg C ha⁻¹ with conversion to agricultural production (Huggins et al., 1998). This resulted in a loss of nearly 50 Mg C ha⁻¹, representing about 27% of the total carbon in the soil profile to 1.5-m depth (DeLuca and Zabinski, 2011).

The SOM content in cultivated prairies may continue to decline or it may be stabilized, depending on how the land is managed. Declining SOM contents are associated with intensive tillage and frequent fallow periods in the Great Plains region. Intensive tillage refers to a combination of primary (plowing) and secondary (harrowing) operations, which may occur in the spring or fall. Tillage has several advantages because it aerates the soil, prepares the seedbed for planting, disrupts weeds and speeds up soil warming. It also loosens compacted layers and improves water infiltration. The main disadvantage of tillage is that it increases carbon loss due to soil biological respiration by accelerating decomposition of plant residues and disrupting aggregates that contain occluded organic matter. Consequently, the SOM contents tend to be lower in intensively tilled soils than in those with conservation tillage in semi-arid and arid regions. Plowing reduced the soil organic carbon content by 40% in the native prairie and by 27% in a restored prairie (cultivated for 37 years, then replanted with crested wheatgrass, *A. cristatum* (L.) Gaertn., for 11 years). When conservation tillage (no-tillage) occurred on the same sites, the soil organic carbon content declined by 20% in the native prairie and by 4% in the restored prairie (Doran et al., 1998). The benefit of conservation tillage methods such as no-tillage and zone tillage, which disturbs the soil in only a narrow band directly below the crop row, is that these methods preserve the soil structure and leave surface litter as a slowly-decomposing mulch that also retains water.

A fallow period occurs when arable land is not planted with a cash crop during the growing season. Traditionally, the aim is to improve soil fertility and increase soil moisture, because vegetation growing on fallow land is tilled into the soil to retain nutrients and water, rather than exported from the field. However, fallow periods are associated with loss of SOM, particularly when coupled with intensive tillage. Doran et al. (1998) observed that 32% of soil organic carbon was lost from topsoil (0–30-cm depth) after 27 years of winter wheat–fallow cropping in western Nebraska. Modern conservation tillage systems, coupled with greater availability of irrigation in the Great Plains region and the development of drought-tolerant crop varieties, has greatly reduced the need for fallow. From an economic perspective, it is more profitable to grow oilseeds and pulses in rotation with cereal crops in the semi-arid regions of former prairie grasslands. Diversifying the crop sequences in the Great Plains region is expected to improve soil fertility and biological functions, and may replenish the SOM, depending on the crop rotation. Annual crops like lentils (*Lens culinaris* Medik.), field pea (*Pisum sativum* subsp. *Arvense* (L.) Asch.), flax (*Linum usitatissimum* L.) and canola, rapeseed (*Brassica napus* L.) have a limited effect on SOM because of their relatively low residue input. Appreciable gains in soil organic carbon are recorded when perennial crops (+6.2% soil organic carbon) and cover crops (+12.5% soil organic carbon) are included in the crop sequence because these crop species produce more roots and other residues than annual cereals and legumes (King and Blesh, 2018).

Although SOM content can be regenerated by adopting conservation tillage and diverse crop rotations in the former prairie grasslands of the Great Plains, drier hillslopes that erode when cultivated are still vulnerable to SOM loss. Restoring the SOM in erodible areas of the landscape is possible, but the land must be taken out of cultivation and a permanent vegetative cover must be established. The Conservation Reserve Program is a government-subsidized program in the United States that pays landowners to re-vegetate erodible cropland for 10–15 years. One way to achieve this is to restore the native prairie by applying a ‘seed-hay’, the aboveground biomass containing dried seeds from a natural prairie remnant, on the surface of a cultivated field (Fig. 9).

Fig. 9 Prairie strips, the light-green strips in cropland with dark green foliage, are strategically revegetated in perimeter areas of crop fields, eroded hillsides, terrace channels, on pivot corners, along waterways, or in low-lying, waterlogged areas. This is an affordable and environmentally beneficial agricultural conservation practice, supported by the Conservation Reserve Program, that supports biodiversity, regeneration of the soil organic matter, prevents soil erosion and protects water quality. Photograph by Omar de Kok-Mercado, Iowa State University ©2020.

Fig. 10 Riparian buffers are vegetated areas near streams where trees, shrubs and other perennial plants are grown to shade and protect the stream from the impact of adjacent land uses. This is an affordable and environmentally beneficial agricultural conservation practice, supported by the Conservation Reserve Program, that supports biodiversity and prevents soil and streambank erosion, thereby improving water quality in the aquatic environment. Photograph by Seneca Conservation District ©2022.

Prairie restoration effectively increased the soil organic carbon level to 68–74% of the carbon content in the native prairie, whereas the continuously cultivated soil had 50% or less soil organic carbon than the native prairie in Texas (Potter and Derner, 2006). The Conservation Reserve Program also encourages the planting of filter strips, riparian buffers, grassed waterways, field windbreaks, shelterbelts and salt-tolerant vegetation, while the complementary Wetland Reserve Program promotes restoration of wetlands and flood-prone areas (Fig. 10). Replacing cropland with woody species promotes carbon sequestration because carbon accounts for about 45% of the structural components of trees and shrubs. In undisturbed environments, woody species will increase the soil organic carbon, but the carbon gain depends upon the area covered by woody plants, the species planted and disturbances such as fire and grazing that remove part of the woody biomass. Since their inception, the Conservation Reserve Program and Wetland Reserve Program have resulted in the voluntary conversion of approximately 11 million hectares of farmland into conserved lands. This has had the effect of increasing SOM, preventing soil erosion, and protecting vital waterways and wildlife habitat.

Soil change due to element imbalance

Element imbalances are observed in nature from heterogeneities in the geological processes that are responsible for soil formation, coupled with climatic conditions. For example, soils may have large inherent salt concentrations because the parent materials contained salts: calcium, magnesium, sodium, iron (Fe), manganese (Mn) and aluminum (Al). These elements associate with carbonates, bicarbonates, chlorides, sulfates and phosphates, which are dissolved through weathering to release salt ions into the soil pore water. Salinity problems in cultivated soils generally arise because the water source used for irrigation has an elevated salt concentration with an electrical conductivity $>1 \text{ dS m}^{-1}$. Poor drainage of naturally saline soil is another factor contributing to salinity. This occurs when water containing salts moves towards the soil surface, rather than leaching through the soil profile. As the water evaporates, salts are left behind as precipitates and form salt layers and crusts near the soil surface.

Plant growth is suboptimal in saline soils because of osmotic stress. This causes water to move from the weakly saline cytoplasm of plant root cells into the saline soil pore water surrounding the roots. This inhibits the transport of substrates and cofactors into plant cells and leads to the accumulation of reactive oxygen species that cause oxidative stress in the plant. The osmotic effect depends on the dominant cations present, with $\text{Na}^+ > \text{Ca}^{2+} > \text{Mg}^{2+}$ because large Na^+ concentration in cell walls can induce Ca^{2+} and K^+ deficiencies. Osmotic effects are also associated with salt-associated anions and $\text{Cl}^- > \text{SO}_4^{2-}$ because of their potential toxicity and interference with NO_3^- uptake in salt-sensitive plant species. Salt imbalance can be corrected by irrigating with desalinized water and adding fertilizers to balance the plant nutrient requirements, but this increases the crop production costs. Clearly, global change leading to soil salinization is a threat to the sustainability of the world's food supply.

Soil changes due to the accumulation of trace metals that are not essential for plant growth, through natural or anthropogenic processes. Element imbalance is often indicated by the presence of trace metals in edible parts of crops, as well as their biomagnification in food webs, at levels that threaten human or animal health. Some trace metals become elevated in natural

Fig. 11 Element imbalance in cucumber leaves (*Cucumis sativus* L.) exposed to cadmium (Cd) for 20 days. (a) normal leaf with no Cd exposure. (b) chlorotic leaf showing signs of reactive oxygen stress after exposure to 500 μM Cd. From Sun S, Li M, Zuo JH, Jiang WS and Liu DH (2015) Cadmium effects on mineral accumulation, antioxidant defence system and gas exchange in cucumber. *Zemdirbyste-Agriculture* **102**: 193–200. doi: 10.13080/z-a.2015.102.025.

soils due to weathering of enriched parent material. For example, cadmium (Cd) associates with sulfides, carbonates and phosphorites resulting in elevated cadmium concentrations in mafic and ultramafic rocks that contain 0.001–0.60 mg Cd kg⁻¹, as well as black shales with 10–500 mg Cd kg⁻¹ (Page et al., 1987). Geogenic weathering releases a significant amount of cadmium into soil, which readily leaches into groundwater and surface water. Cadmium is a carcinogen for humans and the WHO Guidelines for Drinking-Water Quality recommend a guideline value of 3 μg Cd L⁻¹ in potable water. Anthropogenic sources of cadmium, which is a non-essential element, enter soil through mining, atmospheric deposition of combustion products and application of cadmium-containing fertilizers. This has led to cadmium pollution in soil and groundwater worldwide, exacerbated by the tendency for cadmium to form water-soluble complexes with anions, such as CdCl⁺ and Cd(SO₄)₂²⁻, and associate with dissolved organic matter. Plants accumulate Cd from soil and should be consumed sparingly to avoid negative health outcomes (Fig. 11).

A global assessment of trace metals, also known as toxic elements, reveals more than 5 million sites with contaminated soil. The situation is particularly dire in China where approximately 4 million ha of arable land is moderately or highly contaminated from pollution and more than 25% of the farmland has excessive amounts of cadmium, chromium (Cr), lead (Pb), tin (Sn) and zinc (Zn), leading to a crop production loss of about 10 million Mg per year (Shao et al., 2011). In Europe and the Americas, the cities and industrialized areas are more likely to have soil contaminated with toxic elements from power plants, industries, and heavy traffic. Soil contamination is related to the geographical and socio-economic development, industrial activities, land use, population density and local climate in each area. Several technologies have the potential to decontaminate local soils, depending on the extent of pollution and regulatory limits for each toxic element. Soil washing, electrokinetic remediation, phytoremediation, bioremediation and site stabilization are effective methods of removing toxic elements or retaining them in the soil, to prevent off-site contamination. Control of the anthropogenic sources of metals in the environment, which can be achieved by adopting green chemistry technologies and preventing metal emissions to the atmosphere and waterways, are additional strategies that should reduce soil changes due to pollution in the future.

Element imbalance in cultivated lands is linked to a change in the soil fertility level. It is common to apply agricultural lime, organic amendments and fertilizers to improve soil fertility, since this produces economically profitable yields. However, some amendments are inherently unbalanced in their element composition, making it difficult to choose an application rate that provides the right quantities of macro- and micro-nutrients to match the agronomic crop requirements. This is the case for recycled wastes such as animal manure, municipal wastewater biosolids and incineration ash, which generally have less nitrogen but more phosphorus, nutritive substances and trace elements than required by crops. Annual applications of beef cattle feedlot manure according to local farmer practices provided 1.6–9.4 Mg P ha⁻¹ in a 16-year period, but the barley (*Hordeum vulgare* L.) crop required no more than a tenth of the applied phosphorus (barley harvest removed 0.2–0.6 Mg P ha⁻¹ during the same period; Whalen and Chang, 2001). This resulted in up to 10-fold more plant-available phosphorus concentration in the topsoil of manured soil than unmanured soil, and substantial phosphorus leaching through the soil profile, below the crop root zone. After 25 years of continuous application of beef cattle manure to the same field, there was a linear increase in the soluble salts (Na, K, and Mg) with increasing rates of manure application and more extractable copper and zinc.

Element imbalance in soil is linked to the deterioration of water quality in watersheds, worldwide. Nitrogen that is not used by the crop is lost by leaching, surface runoff and gaseous emissions. Phosphorus leaves the soil through leaching and surface processes (sediment loss and runoff) in quantities that greatly exceed water quality standards. For example, the sediment-associated particulates from agricultural fields in a cold humid region contained as much as 3181 μg P L⁻¹ in surface runoff and 1346 μg P L⁻¹ in surface tile drainage water (Poirier et al., 2012); more than two orders of magnitude above the 30 μg total P L⁻¹ level in eutrophic waters. Eutrophication of aquatic systems that receive excess nitrogen and phosphorus from agricultural runoff is

Fig. 12 Dairy slurry manure applied at a rate that supplies essential plant elements in balance with the needs of the grass-based hayfield, based on the farm nutrient management plan. Judicious use of fertilizer will support crop yield targets while protecting air and water quality. Photograph from Irish Farmers Journal @2018.

associated with cyanobacteria blooms in freshwater systems and coastal estuaries. Blooms of cyanobacteria and other noxious algae are responsible for the closure of recreational fisheries, deteriorating water quality and the loss of biodiversity. Furthermore, hazardous algal blooms produce toxic substances like cyanotoxins that cause acute and chronic health problems in plants, animals and humans, constituting a major risk to public health.

Soil changes due to element imbalance in the essential plant nutrients are detected by regular soil testing, every 3–5 years. To avoid further soil change, which could accelerate nutrient losses into downstream environments and the atmosphere, farmers must follow fertilizer plans that constrain the nutrient inputs to agricultural fields (Fig. 12). Fertilizers must be applied when they are needed by the crop and in close proximity to the roots, for maximum nutrient uptake. Field margins must be stabilized to prevent erosion, trap sediments and retain runoff, often by deliberately planting a buffer with permanent vegetation such as perennial grasses, shrubs and trees. Constructed wetlands and other environmental filters can be built to intercept nutrient-rich water and prevent it from entering downstream waterways. Depending on the jurisdiction, compliance may be achieved through voluntary programs or through regulations and structured policies that limit livestock production and applications of fertilizing materials to vulnerable catchments. The joint efforts of farmers, agricultural planners and watershed managers is essential to prevent soil element imbalances from having a long-term impact on water quality.

Conclusions

Soil change is the result of geological and anthropogenic processes. Soil erosion and SOM loss increase dramatically when undisturbed land is converted for agricultural use. It is possible to halt and reverse soil change by choosing agricultural practices that reduce the frequency and magnitude of disturbances that can destabilize soil structure and decompose SOM. Land forming activities such as terracing and check-dams, coupled with revegetation programs and conservation agriculture practices, have proven an effective strategy to regenerate the soil productivity of fragile landscapes within years to decades. Element imbalances are a soil change associated with human activities such as irrigation, industrial emissions of trace metals and over-application of fertilizing materials. Restoration of soil with an element imbalance will take years, but is possible with improved irrigation practices, nutrient management plans, and application of remediation technologies to contaminated soils. The response of restorative soil interventions to fluctuations in soil temperature and moisture associated with global climate change is difficult to predict and remains a challenge in designing effective strategies to combat soil change. Although soil change is observed at a global scale, solutions must involve local stakeholders who are familiar with and invested in restoring the distinct soil type in their area, considering the topography, climate and goals of the restoration project. Some lands are readily improved after conservation agriculture practices

are implemented, and others require regenerative agriculture solutions. Still other areas should be taken out of cultivation altogether because the land is too fragile to be disturbed, or because it is more valuable as a wildlife or water conservation area. Sustainable land use decisions will determine the future trajectory of soil change, and necessarily involve conversations between landowners, lease-holders, soil specialists, watershed managers and government agencies.

Abstract

Without soil, no life on land is possible because soil provides the means for plant growth and plays a crucial role in water and carbon cycling among others. Human-induced global changes related to climate, land use and management are altering soils. The concepts of ecosystem services and soil capital value them, their functions and prevent their degradation. A major challenge for soil science is to quantify the relationships better between global changes, and soil processes and properties. The aim is to predict soil changes and understand whether soils will continue to deliver the services required in the long-term and to what extent soil management can mitigate climate change.

Key points

- Soil is a dynamic system characterized by feedback loops, linking external forcing variables (or factors of pedogenesis), pedological processes, soil properties and ultimately soil functions and services.
- As a result of the complex interactions between climate, land-use and or management changes acting on various spatial and time scales, the direction, intensity and spatio-temporal pattern of future soil changes remain largely unknown.
- First indications of the effect of global change on a range of soil types, processes and properties have been observed already.
- In the future, effects of global change on soils will largely exceed well identified situations such as the reduction of Cryosols, soil degradation processes (e.g. erosion or desertification) or manageable soil properties (e.g. soil organic carbon stocks).
- With the irreversibility of numerous soil processes, a changed climate that can increasingly remove primary minerals, clay particles and base cations from soil threatens soil fertility, quality and health.
- If land-use or land management changes could be used theoretically to counteract climate change, their practical implementation at the pace and spatial scales of climate change is doubtful and could have counterproductive effects.
- Soil management must be planned and implemented to limit the risk of mutual reinforcement of climate and land-use changes that are already inducing cataclysmic soil degradation under extreme weather events.
- To face these arising and mostly inevitable challenges, there is an urgent need to develop tools and methodologies able to capture the new evolution of soil under global changes.
- The feedback loops between external forcing variables and soil properties are currently insufficiently considered in global modelling approaches, in which the soil compartment is generally poorly described.

Introduction

Soils are open systems produced by a complex combination of processes of input, transformation, transfer and export of materials and energy. Their occurrence and intensity are a function of external environmental conditions, otherwise called factors of pedogenesis. These factors include the parent material, climate, relief, living beings and time.

Under the control of these external environmental conditions (factors of pedogenesis), the physical, chemical or biological processes transform and structure the upper layers of the Earth's crust, i.e. the parent material of the soils, whose initial properties are gradually replaced by more stable constituents and organization. The emergence of these new properties is the basis for the ecosystem functions and services that soils provide to humanity. They also affect how the soil responds to external environmental conditions. For example, the physical fragmentation of a hard rock will gradually favor the infiltration of water into the soil and

modify the pedoclimatic conditions; the redistribution of soil particles by erosion will modify the relief; the formation and deepening of the soil will allow its colonization by new plant or animal species which will, in turn, participate in the processes of alteration of the geological substrate. The soil is therefore a dynamic system characterized by feedback loops, linking external forcing variables (or factors of pedogenesis), pedological processes and soil properties. Thus, any modification of the external forcing variables is likely to modify some pedological processes and properties, which in turn will change how the external variables affect the soil depending on thresholds, positive or negative feedbacks or even hysteresis.

From the pedological factors, two – climate and vegetation – have constantly changed through time, notably over the most recent period, in which humans have strongly affected both and will continue to do so in the near future. These changes, also known as global change, have been shown to affect a range of soil properties with some changing rapidly and others gradually (Rounsevell et al., 1999). Agriculture, for example, affects soil rapidly, at a decadal to century time scale (Cornu et al., 2012; Guo et al., 2010; Montagne et al., 2016) and, in many cases, in an irreversible way (Sombroek, 1990; Rounsevell et al., 1999; Montagne et al., 2016). The effects of climate change on soils are more difficult to identify and quantify. However, its impacts may have serious consequences for soil productivity and sustainability of agriculture and forestry as well as the stability of our infrastructure. The changes induced in the soil may in turn act on land use through changes in fertility or on climate via the release of greenhouse gasses. These feedback loops are currently not considered sufficiently in global modelling approaches, in which the soil compartment is generally poorly described.

Therefore, quantifying the impact of global change on soils is a challenge that must be addressed. A major difficulty in addressing this is the large uncertainty about the kinetics of natural soil processes. Consequently, the direction, intensity and spatial distribution of change in the soil under global changes, and their consequences on the delivery of soil services and human well-being still remain largely unknown.

Global change, the dynamics and impact on the fluxes of matter and energy responsible for soil evolution

Global change and its dynamics

The concept of global change, defined in the 1970s, considers human activities as part of the planetary system together with atmosphere, biosphere, hydrosphere and the geosphere. It can be divided in two main types of change: climate change and land use changes.

Climate change caused by anthropogenic emissions of greenhouse gasses is widely recognized, and has resulted in a noticeable increase of the Earth's surface temperature of 0.85 °C since 1880 (Fig. 1). This increase is responsible for the increasing temperature of permafrost areas since the 1980s and a decrease in ice mass and snow cover in most regions, with noticeable consequences for the hydrological regime. In addition, an increase in rainfall has been observed since the beginning of the 20th century in the Northern hemisphere, but with no clear change recorded elsewhere. A change in the frequency of extreme events has been recorded with a decrease in cold extreme events, and an increase in hot extreme events and strong rainfall events (Jia et al., 2019). Regardless of the

Fig. 1 Climate change represented by the relative temperature increase 1951–1980 (NASA data: https://data.giss.nasa.gov/gistemp/graphs_v4/) and global land-use change represented by the surface area converted to soybean and palm oil plantations (FAO data: <https://www.fao.org/faostat/en/#home>) between 1961 and 2020.

Fig. 2 Global change and examples of time steps in soil change (days to millenia).

climate scenario considered, these trends are predicted to continue over the 21st century together with a decrease of rainfall in the arid medium latitudes (Hartmann et al., 2013). An increase in the speed of such progressive changes or even abrupt changes in temperature or precipitation pattern, however, cannot be completely excluded, at least locally, as a result of the atmospheric CO₂ (carbon dioxide) accumulation or climatic break points such as the melting of polar ice caps or changes in ocean global circulations. Gradual changes in temperature and precipitation will induce slow, low amplitude and continuous modifications in soils, whereas extreme events will induce rapid, large amplitude and irregular changes, all of which will accumulate over time (Fig. 2).

Land cover is the biophysical state of the Earth's surface and immediate subsurface. *Land use* involves both the manner in which the biophysical attributes of the land are manipulated and the purpose for which it is used. In other words, land use can be described by the terms 'forestry, parks, farmlands, etc.' as well as by biophysical manipulations such as the use of fertilizers, logging, change of forest species composition, etc. Purely natural disturbances of the land cover, e.g., wildfires have caused large-scale changes like the loss of tree canopy and gain in short vegetation in large patches of boreal Canada, eastern Alaska and central Siberia (Song et al., 2018). However, a much stronger force for change is from human impact. Land-use change is traditionally a local-scale human practice with an annual time step (e.g., deforestation of a plot), its evolution at the global scale has however a decadal to century time step (Fig. 2).

Today, as much as 50% of the Earth's ice-free land surface has been transformed, and virtually all land has been affected in some way by such processes as co-adapted landscapes, climate change, and tropospheric pollution (Turner et al., 2007). The *Millennium Ecosystem Assessment* (2005) states that, while these changes in land uses are not recent, they have been more rapid and extensive since the 1950s as illustrated by the exponential increase in surface area cultivated with soybean (*Glycine max* (L.) Merrill) and palm trees (Arecaceae) during that period (Fig. 1). Nevertheless, a global increase in tree cover has also been observed from 1982 to 2016 together with a reduction in bare soil. The net gain in tree cover was mostly due to increases in the continental and polar regions, and across all climate domains for montane systems (Song et al., 2018). This increase counteracted losses of tree cover in the tropics and in many arid and semi-arid ecosystems where increasing conversion to intensive agriculture is occurring. In northern temperate countries, the surface area dedicated to agriculture has tended to decline while the intensification of agriculture continues to produce more food on smaller areas of land for an increasing human population, and a new challenge of biomass production to substitute fossil fuels emerges. On a positive note, new agricultural diversification practices are emerging worldwide (crop and non-crop rotation, and diversification, various forms of conservation agriculture, organic farming, etc.), many of which show a win-win situation in the relationship between crop yields and multiple ecosystem services (Tamburini et al., 2020). The area under alternative farming systems is still small (~72.3 million hectares of the ~5 billion hectares of agricultural land worldwide are under organic farming) but steadily increasing (FAOSTAT data). In Europe, for example, the area under organic farming currently constitutes around 9% of all agricultural land (Eurostat data).

Overall, land use and land cover changes are considered to be the major causes and consequences of global change on land. Song et al. (2018) estimated that from 1982 to 2016, of all land changes, 60% were associated with direct human activities and 40% with indirect factors such as climate change (e.g., woody vegetation growth in the Arctic). Land use and land cover changes are estimated to have contributed 25% of cumulative carbon emissions to the atmosphere since industrialization (Friedlingstein et al., 2020). Conversely, climate change affects cultivation in many regions of the world (Jia et al., 2019). Indeed, the continuing increase in

global temperature, and the shifts in precipitation patterns in turn affect the net primary production and biome distribution. These complex interactions between climate and land-use changes lead to a complex spatial and temporal distribution of their impacts on the environment at the global scale. Both changes acting synergistically or antagonistically on net primary production, decomposition, leaching and other soil forming factors and processes, will undoubtedly alter the development of soils in ways that are difficult to predict.

Impact of global change on soil stocks, structure and fluxes

Soil is made up of organic and mineral solid phases (or soil stocks) that are spatially organized (soil structure) and form pores, within which water, gas and heat transfers take place. It is also the site of significant biodiversity, which interacts with the soil's solid phases and their structure. Both, climate and land use changes can act directly or indirectly on these soil stocks, structure and fluxes.

By increasing air temperature and modifying precipitation, climate change strongly affects the soil water regime and plant growth, and thus acts indirectly on the biologically mediated soil processes. An increase in annual precipitation leads directly to increased runoff and infiltration, while increases in temperature affect evaporation and transpiration. Temperature and water supply influence solute chemistry and rates of weathering through thermodynamic and kinetic interactions between minerals and solutions, with warmer and wetter environments experiencing higher rates of weathering (Rounsevell et al., 1999). Both air temperature and precipitation have a direct effect on organic matter turnover. Climate, through its control on plant community distribution, has an indirect effect on the quantity and quality of organic matter inputs into soil (Fig. 3).

As mentioned above, land-use change includes a change in vegetation (land cover) as well as a large variety of management practices from tillage, irrigation, fertilization and amendments to more intrusive modifications such as artificial drainage or soil

Fig. 3 Impact of global change on soil stocks (including soil biodiversity), structure and fluxes of matter and energy in soils, and their consequences for the evolution of soil processes.

artificialization (mainly urbanization, mining, industrialization and traffic), and soil construction. Large gaps in knowledge related to the effects of land management persist, in particular for human-induced changes in terrestrial ecosystems that do not result in conversions of land cover. The impact of land use on soil stocks, organization and fluxes is therefore much more diverse than that of climate change and cannot be described in detail here mainly because of the current lack of understanding on this topic. Nevertheless, three main categories can be identified: i) practices that act mainly on soil stocks like fertilization, amendments and harvest; ii) practices that act mainly on soil organization and fluxes like irrigation, drainage and tillage, and; iii) land cover change (forestation, deforestation, artificialization, etc.) that act on soil stocks, organization and fluxes.

Changes in land cover induce direct changes in biotic diversity, actual and potential primary productivity (and therefore biogeochemical cycling), runoff and rates of erosion. The increase in tree cover and reduction of bare soil described above (Song et al., 2018) suggest that globally we could expect an increased accumulation of soil organic carbon (SOC) and potentially an increase in weathering with greater root activity. However, this net gain results from a net loss in the tropics that is outweighed by a net gain in the non-tropics. Thus, in the tropics, where deforestation and conversion of forests to farmland are prominent, a loss of SOC and soil by erosion (a destructive process) can be expected (Fig. 4). Tree species selection can also affect various chemical and physical soil properties such as the interception of precipitation (less for evergreen species), water repellency of the forest floor (higher for coniferous species especially under dry conditions), mineralization and accumulation of organic matter and nutrients, soil pH (generally lower for conifers) and finally mineral weathering (Fig. 3). Overall, the effect of tree species selection on soil properties depends on other environmental variables, e.g., climate and soil mineralogy (Augusto et al., 2014).

Soil artificialization brings elements to the soil by atmospheric deposition (airborne deposits) or by allochthonous material of natural or artificial (rubbles notably) origin. This results most often in changes in soil pH, increases in stoniness and decreases in SOC compared to natural soils, and in some cases – in the formation of a totally new soil type – Anthrosol (Cornu et al., 2021) (Fig. 3).

Fertilization, amendments and harvest mainly act on soil stocks. In forests, harvest reduces standing biomass and soil C stocks, especially when wood residues are removed. The effect of crop harvest is mixed, and often depends on the presence and intensity of pre- and post-harvest management practices (Singh et al., 2018). Fertilization is designed to increase plant productivity, which in turn increases C-inputs to the soil and ultimately the exchange of C between land and the atmosphere. In addition, N fertilization of croplands can lead to soil acidification, when not countered by liming, as demonstrated in Chinese soils, which experienced a 0.2- to 0.3-unit pH decrease in 20 years (Guo et al., 2010). Potassium and N fertilization have been shown to influence exchanges between the soil solution and the soil mineral phase with significant effects on clay mineralogy (Matocha et al., 2016).

Tillage, irrigation and drainage act mainly on the soil structure and fluxes that in turn modify soil stocks, including soil biodiversity. For example, tillage, designed to maintain soil porosity and control weeds, directly affects water fluxes in soils but it also has numerous indirect effects. It reduces soil biodiversity and modifies its composition, for example, the bacteria to fungi ratio or the relative abundances of epigeic, endogeic and anecic earthworms through various mechanisms among which the burying of soil litter is of primary importance. Plowing disrupts aggregate structure, aerating the soil, activating microbial decomposition, releasing nutrients from organic matter and thus depleting SOC. Some evidence indicates that for most soil types adoption of

Fig. 4 Climate (temperature and rainfall) and trends in land-use change for the main Köppen-Geiger climatic zones and resulting vulnerability to global change of the dominant soils. Blue represents rainfall, yellow temperature, green forest area, brown soil vulnerability. In arid and tropical zones the solid blue line describes precipitation in Africa and the dashed line South America. Increasing soil vulnerability is due to thawing in polar areas, weathering and leaching of base cations in the temperate zone, salinization or erosion in the arid zone and erosion after deforestation in tropical areas. In the cold zone, the limited soil vulnerability is due to either an advanced stage of weathering (Podzols, World Reference Base; Spodosols, Soil Taxonomy) or a strong buffering capacity (Chernozems, WRB; Mollisols, Soil Taxonomy).

no-tillage practices after tillage-based management does not significantly increase SOC stocks (Powlson et al., 2014), but changes its depth distribution. No-tillage does, however, generally reduce soil erosion.

Irrigation significantly enhances plant productivity where water limits plant growth with variable secondary consequences on SOC inputs and storage. By increasing water inputs, irrigation increases soil moisture, water fluxes through soil, and can generate anoxic soil conditions when water is in excess. Dissolved elements or particulate matter are brought into soil with irrigation water, some of them being quite relevant in soil development such as salts or contaminants, which can lead to soil salinization.

Similar to irrigation, soil drainage primarily affects water fluxes in soils because it is intended to eliminate excess water to improve soil trafficability and productivity. However, by decreasing soil moisture and promoting better aeration than under conditions that formerly experienced anoxic periods, drainage tends to favor SOC depletion rather than SOC storage, especially in organic soils. By removing excess water from an initially largely closed soil system, drainage increases flows of water and dissolved and particulate matter through and out of soils.

Anticipated soil changes due to global change

Soil resilience and vulnerability to global change

At the global scale, climate is the main factor for soil formation. There is a close dependence between soil processes and properties with soil temperature and soil moisture. Five main zones are commonly differentiated from polar to equatorial climates on the basis of the current global soil distribution (Fig. 4). Soils from very cold climates are characterized by water that occurs primarily as ice and by cryoturbation processes. Cold and humid environments are dominated by the podsolization process, in which the degradation of soil organic material is hindered by cold temperatures, and the percolation of organic acids completely leaches base cations from the soil and dissolves primary weatherable minerals. Toward the mid latitudes, with higher soil temperatures and precipitation, moderate leaching of base cations and transport of particulate matter dominate soil formation (argiluviation, solodization, Fig. 3). The most humid and hot climates of the tropical zones are characterized by ferrallitization involving fast mineralization of soil organic matter, almost complete chemical weathering of primary minerals, strong leaching of solubilized base cations and silicon (Si), and the accumulation of secondary kaolinite, iron (Fe) or aluminium (Al) oxides. In contrast to the humid climates of boreal, temperate and tropical zones, in which the soil formation is dominated by export of materials, that under drier climates involves the accumulation of organic matter (melanization), secondary carbonates and gypsum (calcification), secondary Si (silicification) or various kind of soluble salts (salinization). Despite early recognition of the importance of climate on soil formation, it has in general been ignored in climate change research with the exception of some rare, mostly qualitative, and descriptive studies (Sombroek, 1990; Rounsevell et al., 1999).

Nevertheless, several consequences of climate change may be inferred from the zonal distribution of soil such as: (i) a marked reduction of cryoturbation processes in the current polar climatic zone (Meredith et al., 2019; Fig. 4); (ii) an increase in organic matter turnover and leaching of base cations in either particulate or dissolved forms from the polar to humid cold and temperate zones where temperatures and precipitation are predicted to increase (Fig. 4); and (iii) decreasing organic matter inputs into soils and increasing accumulation of soluble salts of Na (sodium), Ca (calcium), Mg (magnesium) and K (potassium) in arid mid-latitude and subtropical zones where temperatures and precipitation are predicted to increase and decrease, respectively (Fig. 4). The accumulation and leaching of base cations are both theoretically possible under climate change. However, losses in base cations are almost irreversible, therefore, climate change is more likely to induce losses of basic cations and reduce soil fertility than the reverse. Enrichment in basic cations and subsequent improvement in soil fertility may be expected only in the case of soil rejuvenation, if unweathered materials are newly exposed at the soil surface. Such massive rejuvenation has occurred in the past, for example, in northern temperate areas after the last deglaciation, or in tropical areas after aridification.

At the extremes of the climate gradients, where climate change is most severe, thawing of Cryosols (World Reference Base; Gelisols in Soil Taxonomy) in polar areas and desertification in semi-arid to sub-tropical areas have already been observed. In the mid-latitudes, vegetation shifts to the north have been detected, as well as increases in surface and subsurface soil temperature in continental Europe (Khudiyakov and Reshotkin, 2017). Such changes in the most dynamic soil properties are probably the first recordable signals of deeper changes affecting not only soils at the extremes of the climate gradient but also soils under all types of climates. The speed of these changes is, however, poorly understood.

In soils that will experience increased weathering of primary minerals or leaching of base cations, three main situations can be distinguished. Soils already completely depleted in primary minerals and base cations (e.g. Podzol and Ferralsol, World Reference Base; Spodosol and Oxisol, Soil Taxonomy) are likely to be affected little by climate change when not subjected to erosion induced by land-use change (Fig. 4). Soils rich in carbonates, clay minerals, or soil organic matter (e.g. Chernozem, World Reference Base; Mollisol, Soil taxonomy), which act as buffers for soil processes such as argiluviation, podzolization or chemical weathering, should be resilient to climate change (Fig. 4) provided that their stocks of these elements are not totally depleted. Exhaustion of these stocks would represent a clear threshold for the future evolution of these soils. The kinetics of dissolution of carbonates or clay minerals, or turnover of soil organic matter are key properties to consider in their evolution. For soils already poor in these constituents, the buffering capacity of the soil will be reduced quickly and the threshold reached rapidly. These soils are expected to have a limited resilience to climate change (Fig. 4). This is especially the case for large areas of non-calcaric, clay-poor Cambisols (Inceptisols) and Luvisols (Alfisols) (World Reference Base; Soil Taxonomy) in the cool, northern regions, which are among the most productive soils

on Earth. Currently their development is limited by their young age and cool climates, but it could be significantly and very rapidly affected by increasing temperatures and precipitation.

Human effects on pedogenesis are mainly discussed from a theoretical point of view, and quantification of the consequences on soil evolution remain fragmented. In the body of research studying human impact on soils, most deal with: (i) soil degradation processes such as erosion, salinization and desertification, or soil contamination that are directly and strongly linked to human practices; (ii) a single soil property taken individually such as soil porosity, soil water retention, soil organic carbon or earthworm populations to name just a few; and finally, (iii) time scales rarely exceeding a few years (Richter et al., 2007). With its pivotal role on climate change and soil functions, changes in soil organic carbon contents have been widely studied, including time spans ranging from decades to centuries. It has recently been demonstrated, however, that human activities do not only affect soil organic carbon contents and related soil degradation processes, but also most other soil properties. Among these properties, carbonate or clay contents are of particular interest because of their capacity to buffer soil changes (Montagne et al., 2016). Furthermore, a large range of soil processes from podzolization to argiluviation in humid temperate climates is affected (Cornu et al., 2008; Montagne et al., 2016).

One of the main difficulties in identifying possible trajectories for human-induced soil evolution relies on the multidirectional impacts that land use and management changes can have on the buffering of soil properties and consequently on soil resilience. For example, afforestation is known to protect soils physically from rainwater, to increase soil organic carbon content and to contribute to the biological enrichment of base cations and consequently to increase soil resilience. At the same time, afforestation also favors weathering and soil acidification, particularly under coniferous forests, which can reduce soil resilience (Cornu et al., 2008). Similarly, N-fertilization or nutrient export through harvests hastens soil acidification in conventional cropping systems (Guo et al., 2010) and reduces soil resilience, but liming practices increase soil pH and improve soil resilience (Montagne et al., 2016). Finally, irrigation can lead to either leaching or the addition of base cations or clay particles depending on the quality and management of irrigation water. Human occupation and activities will have very contrasting, sometimes opposite, effects on soil evolution. They will depend on the precise combination of chosen practices and of their practical implementation as evidenced by the almost unlimited diversity of Anthrosols (World Reference base).

Impact of global change on soil: Synergy or antagonism?

Climate and human induced changes in land use and management may mutually reinforce each other. This is, for example, the case in semi-arid areas where the decreasing amounts but increasing intensities of rainfall lead to enhanced erosion and where deforestation for cultivation or (over)grazing exerts pressure in the same direction. This is also the situation in areas where rainfall is increasing and where extensive soil sealing prevents the infiltration of rainwater into soils. These two effects combine and cause flooding and landslides. When combined with events of extreme intensity or with soils of low resilience, synergies between climate and land use or management changes can give rise to extreme phenomena as exemplified by major wildfires in Australia, Canada, Greece, Russia or the United States, and by massive landslides and floods in the South of France or more recently in Germany.

Land use and management changes can, however, also counteract the impact of climate change. One example from temperate regions is the increase in tree cover, which could partially or totally offset the increased turnover of organic matter caused by the increase in temperature. In cultivated fields, practices that bring organic matter and other amendments to the soil surface may be of interest to regulate the stock of SOC, carbonates, clay minerals or base cations. For SOC, the “4 per 1000” initiative promotes land use and management changes that could offset the impact of the agricultural sector on climate change or even mitigate it. Although theoretically possible with soils, the practical mitigation of the effects of climate change suffers from several limitations. First, the effects of climate change are already being observed and affect large areas over the world, but the adoption of practices to counteract them depends on political, economic and sociological conditions that will be unlikely to evolve at the pace and spatial scales of climate change. The practice of N fertilization has, for example, induced the acidification of Chinese soils in the past 20 years (Guo et al., 2010) despite the fact that liming practices have been well known and used for millennia to maintain soil pH. Furthermore, when practices to counteract change rely on finite resources (e.g., phosphate fertilization) or consume energy (e.g., for extracting, transporting or spreading limestone amendments), their large-scale use will rapidly become unsustainable or have counterproductive effects on climate change. If changes in soil use and management are insufficient to mitigate climate change and its impacts significantly and globally, they must be designed and implemented to avoid further negative consequences.

Assessing soil change under global change, a scientific challenge

As discussed above, some soil properties are already changing whereas others will change as a result of the complex feedbacks between the factors of soil formation, the direction and intensity of soil processes and soil properties. As far as the dynamics of soil properties are concerned, two types of soil properties are defined: those that can be managed by human activities (SOC, pH, nutrients, topsoil structure, i.e., the macroscopic organization of solid grains and pores) and the so-called inherent soil properties (texture, mineralogy, soil type, soil depth, horizon sequence, structure at depth). When addressing global change, time steps from a few decades to a century are important (Fig. 2). Despite early recognition of the dynamic nature of all soil properties on a time scale ranging from several decades to a century, inherent soil properties are still considered stable in time. This is probably due to the lack of systematic research on the multi-decadal impact of land use and soil management on changes in soil properties. Disregarding

this dependence of the soil's inherent properties on time, which strongly affects the manageable ones as demonstrated for SOC (Mathieu et al., 2015), induces errors in predicting the dynamics of the manageable properties.

The quantification of medium to long-term changes in soil properties, in particular of inherent properties, is challenging. Long-term field experiments are the tools of choice for studying evolution of soil inherent properties (Filippi et al., 2016), however, they are too rare to provide an exhaustive characterization of all the potential combinations of soil resilience with changes in climate, land use or management. Another classical approach in studying change in soil is the use of soil sequences, in which only one pedological factor changes while others remain as constant as possible. This assumption is, however, sometimes difficult to verify (Filippi et al., 2016). Studies of soil sequences that vary mainly with climate (so called climosequences) were performed along latitudinal or altitudinal gradients. They demonstrated a significant impact of climate on soil evolution. However, in this approach both temperature and rainfall evolve jointly in a way that may differ from that induced by climate change and the change of atmospheric CO₂ concentration is not considered. Some studies have also shown by an analogical approach with artificial drainage as a proxy for the projected increase in soil drainage due to climate change in temperate Luvisols (Montagne and Cornu, 2010), that the impact of climate on soil evolution could be significant over a few tens of years. Conversely, anthroposequences have been used to quantify the effect of different cultivation practices on soil, notably tillage reduction, artificial drainage, organic amendments among others. However, these studies were mainly performed on a local scale and for a few types of soil only. When considering global change, other approaches have to be considered, for example, monitoring networks that have been implemented increasingly over the last few years at the national scale. Their implementation is time- and resource-consuming, however, and their results do not elucidate the effects of global change unless at least two campaigns separated by a few decades are available at the global scale. A last, but challenging, option is the reuse of legacy data that are available worldwide (Filippi et al., 2016).

All these approaches involve studying past changes. They may be used to provide future projections, but because future combinations of climate, land use, and soil type are unknown, they may fail to deliver a good result. Modelling approaches are thus needed.

Two main types of modelling approaches exist in the literature: (i) empirical or statistical, and (ii) more deterministic models. Purely empirical or statistical predictions, despite being highly appropriate for applied purposes and decision-making, may not be useful for predicting future states of soils over the long term (century or more). Alternatively, deterministic modelling enables us to describe the interaction of soil processes with the pedological factors. Most of the existing models, however, depict the effect of various agricultural practices on the evolution of a single soil property (e.g. SOC content, sensitivity to erosion). Although they do not consider important soil internal feedbacks, they often integrate other soil properties in the form of input data (e.g. clay content in SOC dynamics models). A few attempts at pedogenesis modelling developed over the last decade explicitly consider the fluxes of solid constituents, solute and water transfers, agricultural practices and the feedback loops between soil functioning and soil structure at the profile (e.g. SoilGen, Finke, 2012) or the landscape scale (e.g. MILESD, Vanwalleghe et al., 2013; HydroLorica, van der Meij et al., 2019). They could, therefore, simulate the effect that changes in climate or human practices could have on soils because they (i) consider interactions between physical and chemical processes; (ii) take into account climate factors, land-use and agricultural practices as boundary conditions; and (iii) provide the depth distribution of a large range of soil properties. They do not, however, generally contain a dynamic description of the other compartments of the ecosystem, notably plant development. On the other hand, dynamic global vegetation models (DGVM) have been developed to predict the impacts and feedback of climate and land use on vegetation and carbon budgets. The DGVMs notably predict primary production, water, carbon and nitrogen fluxes to the atmosphere and surface water, as well as their storage in the soil (Le Quére et al., 2018). However, in these models, for which soil data availability is a key issue, soils are the least well described compartment (Dai et al., 2019). This situation leads to significant biases in DGVM predictions (Folberth et al., 2016), that can exceed the effect of climate variability (Koven et al., 2013). Therefore, while these models represent the best tool we currently have for simulating the long-term effect of human-induced global change on soil, they require a better description of the interactions and temporal evolution of soil properties.

Concluding remarks

In soil science, climate and human activities were recognized very early as significant factors for soil formation, but the understanding of current climate and land use or management changes on soil is limited to: (i) a subset of soil degradation processes; (ii) manageable soil properties, in particular organic carbon concentration and stocks; and (iii) relatively short time scales in general. In addition, the precise dynamics of how soil responds to climate or human impact is still poorly understood. However, global change has already had an impact, and will continue to affect all soil fluxes and stocks with consequences not only on the manageable soil properties but also on a large range of inherent soil processes and properties. Moreover, the examples given above show that soil change may be faster than previously thought, especially for the inherent properties.

Predicting the impact of global changes on soil processes and properties remains a challenging task given (i) the interlinking of different and complex changes in patterns of climate, land use and management as well as of soil resilience, (ii) the shift from a pedogenesis driven by slow, low amplitude and continuous changes in soils to a pedogenesis driven by more rapid, large amplitude and irregular changes due to the increasing frequency of extreme climatic events and the globalization of land use and land management abrupt changes, and (iii) the current lack of adequate tools to assess unprecedented combinations of climate, land use and management on a set of interacting soil processes and properties. Understanding these complexities is, however, becoming urgent as climate or human-induced changes in soil properties will inevitably have either positive or negative effects on the future

delivery of soil-based ecosystem services such as biomass production, water storage and purification, climate regulation, erosion and flood regulation, etc. Beyond this complexity, there is no doubt that climate change is more likely to induce additional removal of primary or clay minerals than the reverse. Similarly, while examples of soil deterioration due to human activities are frequent, examples of soil recovery are less common. For such reasons, climate and land use changes are considered as two major factors for soil degradation. Halting human-induced soil degradation is unlikely to be sufficient to mitigate climate change significantly. It should, however, be at least the minimum objective to avoid or reduce cataclysmic changes and maintain sufficient resilience in the soil to climate change. This would give scientists and practitioners enough time to understand better the impact of global changes on soils, and to develop better approaches and tools that could help us maintain soil ecosystem services to at least the same level as they are now.

Abstract

Fertilizers increase availability of essential plant nutrients in the soil and alter many chemical, biological and physical soil properties. Fertilizers lead to the accumulation of soil organic matter (SOM), but the excessive application of nitrogen fertilizers is deleterious to SOM, may contribute to nitrate pollution of freshwaters and emission of nitrous oxide – a greenhouse gas. Nitrogen fertilizers can also cause soil acidification. Phosphatic fertilizers may contribute to eutrophication of surface waters, and heavy metal impurities in these may contaminate soils. Balanced fertilization positively affects soil organic matter and soil biota; and in general soil microbial life is positively influenced.

Glossary

Ammonification and urea hydrolysis Ammonification is the primary microbial process that converts reduced organic nitrogen to ammonium. In the case of urea hydrolysis, the enzyme urease catalyzes the conversion of urea to ammonia and carbonic acid.

Nitrification Biological oxidation of ammonium to nitrite and then to nitrate. Both steps are carried out by two different types of prokaryotes.

Prophylactic fertilizer use Application of fertilizers as a preventive measure to avoid development of nutrient deficiency in the crop to be grown on the soil.

Recommended fertilizer rate Crop and region specific fertilizer application rates, which result in profits for the farmers based on the cost of fertilizer and income from the crop, together with minimal losses of nutrients to the environment.

Shannon diversity index A measure of diversity that combines species richness (the number of species in a given area) and their relative abundances.

Soil acidification Reduction of soil pH and build-up of hydrogen cations due to production of various acids in the soil, active uptake of some nutrient ions by biota through proton pumps, transformation of nitrogen applied to the soil, and acid deposition on the soil.

Soil Erodibility Measure of the resistance of soil to erosion. Particles in highly erodible soils are readily displaced and transported by water or wind.

Key points

- Mineral fertilizers supply essential plant nutrients but also affect many soil functions both positively and negatively
- A large portion of nitrogen applied to soil as fertilizer converts into organic forms and becomes part of the soil nitrogen pool
- Fertilizers applied to crops at recommended rates promote the production of both above- and below-ground plant biomass leading to the accumulation of soil organic matter
- Fertilizer nitrogen applied at above the recommended rates can accelerate microbial decay of organic matter already present in the soil and also contribute to nitrate pollution of fresh water bodies and emission of nitrous oxide – a greenhouse gas
- Nitrogen fertilizers lead to soil acidification through microbial nitrification of ammonium ions and leaching of nitrate ions from the soil.
- Fertilizers in general positively influence the microbial life in soil
- Fertilizer use reduces soil erodibility through enhanced plant growth leading to soil stabilization and increased organic matter contents
- Heavy metals and radionuclides contained as impurities in phosphatic fertilizers may contaminate soils
- Balanced application of N, P, and K and integrated management of mineral fertilizers with organic manures enhance the positive effects of fertilizers in the accumulation of soil organic matter, biota, and physical properties
- Long-term use of phosphatic fertilizers in intensive agriculture leads to a build-up of surplus phosphorus in the soil and its transfer via runoff results in eutrophication of lakes and rivers

Introduction

Soil is a complex and variable natural resource, critical for life on earth, and natural living medium for the growth of plants. It provides mankind with most of its food, nutrients, and energy needs. It is a habitat for many organisms and constitutes a living system characterized by many complex biological functions that interact with the abiotic, physical, and chemical environment. From the perspective of agro-ecosystems, a healthy soil supports, nurtures and sustains food production with minimum adverse effects on the environment. Soil health is reflected in several management-sensitive soil properties and the ability of soil to carry out different ecosystem functions, respond to agricultural interventions, and thwart processes that degrade it.

In the last century, humans have altered agricultural soils more than in any comparable period in human history. While tillage and irrigation constitute the two major anthropogenic interventions in the functioning of agricultural soils, during the last 70 years the application of mineral fertilizers has resulted in a fundamental change in soil and crop management to improve global food security. Fertilizers were introduced in the late 19th and early 20th centuries, but global nitrogen (N) and phosphorus (P) fertilizer use was negligible in 1900 and increased very slowly to about 7 M nutrient t in 1950. It was only after World War II when large scale production of N fertilizers became possible by the Haber–Bosch process that fertilizer use increased exponentially to support the rapidly growing human population. Thus, massive additions of mineral fertilizers to agricultural soils started only after 1950 (Fig. 1) and it was an integral component of the Green Revolution witnessed from the 1950s onwards in different parts of the world. According to an estimate, increased food production achieved by the application of N fertilizers now supports about half of the global population (<https://ourworldindata.org/fertilizers>, accessed 24 January 2022). However, mineral fertilizers are chemicals that can potentially alter the natural functioning of soils and lead to major and sometimes irrevocable changes in their characteristics.

High yields are obtained by applying recommended fertilizer application rates for different crops. But many farmers tend to apply them at excessive rates to avoid the risk of yield loss from nutrient deficiencies. For example, after the 1980s, in many countries in East and South Asia, fertilizer N consumption increased several fold more than in the North America and West Europe, where levels have either stabilized or decreased since 1990 (Fig. 1). In 2019, China and India, with about 36% of the global population, used 42.45% of the 107.7 Mt. total fertilizer N consumed globally; North America and Western Europe consumed only 16.95% (<http://www.fao.org/faostat/en/#data/RFN>; Accessed 24 January 2022). Fertilizers, particularly when applied in excess, can lead to losses of nutrients from the soil–plant system to the environment and degrade its quality. The challenge ahead is to understand the changes in soil properties from fertilizer use and to manage them to keep soils healthy to support sustainable food production with minimal environmental impact. Efficient fertilizer management and sustainable soil health will ensure production of sufficient food from the land already under cultivation and allow land to be spared for purposes other than agricultural production.

Mineral fertilizers as sources of plant nutrients

Mineral fertilizers are chemicals that contain elements essential for the growth of plants. The three primary plant nutrients supplied in large amounts by fertilizers are N, P, and potassium (K). Chemicals supplying zinc (Zn), boron (B), copper (Cu), iron (Fe),

Fig. 1 Global fertilizer nitrogen, phosphorus, and potassium use from 1961 to 2019. Data source: <http://www.fao.org/faostat/en/#data/RFN>, accessed 24 January 2022.

manganese (Mn), and molybdenum (Mo) to plants are required in very small quantities and are classified as micronutrient fertilizers.

Fertilizers are used to achieve sustainable agricultural production. Global consumption of mineral fertilizers has increased from 11.39 Mt. N, 4.74 Mt. P, and 7.15 Mt. K in 1961 to 107.74 Mt. N, 18.95 Mt. P, and 31.03 Mt. K in 2019 (Fig. 1). In particular, N is vital for high yields because it is required in large quantities for building plant proteins that are essential for converting solar radiation into carbohydrates that control plant growth. The effect of applying fertilizer N to various crops is generally conspicuous in terms of plant growth and crop yields. Therefore, its use has increased from 1961 to 2019 by almost 9.5 times compared to four times for both P and K. Furthermore, to ensure food security, fertilizer N has been heavily subsidized by governments in countries such as China and India resulting in higher than necessary applications to reduce the risk of yield losses from N deficiency. Effects of fertilizers on soils differ depending on rates of application. Nutrient application can be as single-nutrient fertilizers or compound multi-nutrient fertilizers. There are two ways to produce compound fertilizers: (1) by combining two or more ingredients through chemical reaction (complex fertilizers), and (2) by blending two or more granular fertilizers. Their effects on the soil are governed by the amount of nutrients applied, nature of the chemicals in the fertilizer, method of application (soil surface application, band placed or mixed into the soil), general soil conditions (such as temperature, soil water content, soil texture and structure), and environmental conditions at the time of application.

Ammonia produced by the energy-intensive Haber–Bosch process is the most used source for producing different N fertilizers. Urea remains the most commonly used N fertilizer all over the world. In 2018, farmers applied 48.1% N as urea, 20.5% in the form of ammonia and various ammonium salts, and 20.3% as NPK, NP, and NK compound fertilizers (<https://www.ifastat.org/databases/plant-nutrition>, accessed 3 August 2021). When applied to the soil, urea is readily hydrolyzed to NH_4^+ and carbon dioxide by the urease enzyme present in soil. This reaction raises soil pH which may lead to ammonia volatilization of some of the applied urea N. The NH_4^+ -N produced from urea hydrolysis or through applying NH_4^+ fertilizers may be immobilized into soil organic matter (SOM), taken up by plant roots, or converted to NO_3^- through nitrification – a bacterial process dependent on soil temperature, moisture, aeration, and pH. In well-aerated soils, NH_4^+ -N is converted to NO_3^- -N within a few weeks. Plant roots can readily take up and transport both NH_4^+ and NO_3^- ions.

Most phosphatic fertilizers are produced from rocks containing fluorapatite and hydroxyapatite. By treating phosphate-rich rock with strong acids, the P-containing minerals are converted to water-soluble P salts. When the rock is treated with sulfuric acid, normal or single superphosphate fertilizer containing a mixture of monocalcium phosphate and gypsum in about equal proportion is produced. Triple superphosphate fertilizer is produced by treating phosphate rock with phosphoric acid. Nitric phosphate fertilizers containing both N and P are produced when nitric acid is used to solubilize P-containing minerals in the phosphate rock. Superphosphate application to soils results in an acidic reaction. Phosphorus-containing ammonium phosphate fertilizers are produced by reacting ammonia with phosphoric acid. When applied to the soil, diammonium phosphate is basic in reaction while monoammonium phosphate is acidic. However, nitrification of NH_4^+ reduces soil pH a few weeks after the application of either of the two ammonium phosphates.

The two common K fertilizers are potassium chloride (muriate of potash) and potassium sulfate, although potassium nitrate is also used sometimes to supply K to crops. Potassium chloride, the most widely used source of K on farms is mined from rock

deposits left by evaporites in different regions of the world (e.g. Canada). Potassium sulfate is produced by reacting potassium chloride with sulfuric acid. All K fertilizers supply K^+ ions to the soil–plant system.

Effects of fertilizers on the nutrient supplying capacity of soils

Nitrogen

In all soils, the large amount of N retained in SOM is referred to as the soil N pool. Mineral-N (NH_4^+ + NO_3^-) is released from this pool to a smaller pool through mineralization–immobilization turnover, a microbial process controlled by soil temperature and moisture conditions (Fig. 2). Nitrogen applied to soil systems through various input sources such as mineral fertilizer, organic matter and crop residues plus N-fixation and atmospheric deposition, adds to these soil N pools. Nitrogen contained in the soil mineral-N pool can be taken up by plant roots and microbial organisms but is also susceptible to losses by leaching, ammonia volatilization, and denitrification. Data generated using ^{15}N -labeled fertilizers in 93 studies from all over the world show that the average recovery of fertilizer N by harvested grains and above-ground plant residues of rice (*Oryza sativa* L.), wheat (*Triticum aestivum* L.), and maize (*Zea mays* L.) crops is only 44% (Ladha et al., 2005). Remaining N taken up by crop plants is supplied through mineralization of N from the organic N pool in the soil that has been enriched by fertilizer N applications in previous years. Research on 217 fields with grain crops to which ^{15}N -labeled fertilizers were applied, revealed that even with large rates of fertilizer N average plant N uptake from the soil N pool was about 60% (Gardner and Drinkwater, 2009). A portion only of fertilizer N applied to agricultural soils (about 50%) contributes directly to the mineral N pool of which some may be lost from the soil–plant system (Fig. 2). Remaining fertilizer N converts into organic forms to become a part of SOM. Sebilo et al. (2013) showed that 61 to 65% of the one-time application of ^{15}N -labeled fertilizer to a sugar beet (*Beta vulgaris* L.)–winter wheat annual crop rotation on a chalk soil was used by the crops adequately fertilized by unlabeled N during the next three decades. Nevertheless, 12 to 15% of the ^{15}N was recovered in the soil N pool three decades after its application. An important implication of the interaction between fertilizer N and soil N is that a portion of the annual fertilizer N inputs that exceeds the N either removed by the harvested crops or becomes a part of the soil N pool, is vulnerable to losses to the environment. Because some fertilizer N is always incorporated into the soil N pool and becomes available for uptake by crop plants subsequently suggests that unless adequate fertilizer N is applied to crops, the soil N pool will gradually be depleted and soil quality adversely affected. Thus the soil N pool, if not maintained by sufficient fertilizer N and or through organic manure application and recycling of legume residues, will not enable full yield potential and soil biodiversity to be achieved.

Phosphorus

Phosphorus is held by different soil components with a continuum of bonding energies (Syers et al., 2008). The various conceptual pools of soil P and movement of P between pools are shown in Fig. 3. In the soil solution, P is present as orthophosphate ions, principally as $H_2PO_4^-$ and to a lesser extent as HPO_4^{2-} , which are bioavailable for plant uptake. While P concentration in the soil solution at 10^{-4} M is considered high, in P deficient soils it is 10^{-6} M, and in some tropical soils with very poor fertility it can be as low as 10^{-8} M (Syers et al., 2008). In the readily available P pool, which is in equilibrium with P in the soil solution, P is weakly bonded to the surfaces of soil components. Phosphorus is readily transferred from this pool to the soil solution when P is taken up

Fig. 2 Schematic diagram showing the interactions between fertilizer N and soil N, and its effects on crop N uptake and loss.

Fig. 3 Schematic diagram showing the fate of fertilizer P in relation to different P pools in the soil. Adapted from Syers JK, Johnston AE, and Curtis D (2008) *Efficiency of Soil and Fertilizer Phosphorus Use: Reconciling Changing Concepts of Soil Phosphorus Behaviour with Agronomic information*, FAO Fertilizer and Plant Nutrition Bulletin 18. Rome: Food and Agriculture Organization of the United Nations.

by plant roots. In the less readily available soil P pool, it is adsorbed onto the soil matrix or internal surfaces of soil components. Over time P in this pool can revert to the readily available pool. There is also a slowly available P pool, in which P is very strongly bound to soil components through (1) complexation with soil minerals, (2) precipitation as sparingly soluble compounds, or (3) location in the soil matrix and inaccessible to plant roots. Equilibria between different P pools in the soil primarily involve adsorption and diffusive penetration reactions that may be largely reversible, therefore, plant availability of fertilizer P may decrease with time. Reversible transfer of P between the three pools is important for its behavior in soil; only a fraction of the total P applied through water-soluble P-fertilizers remains in soil solution while the remaining P is distributed between the readily- and less readily-available P pools.

Soils rarely contain sufficient P in the soil solution to meet the demand from crops. Phosphorus in soil solution is replenished several times a day from readily and less readily available P pools. Globally, about two thirds of the total agricultural land contains too little plant-available P. To avoid sub-optimum yields of crops associated with P deficiency, farmers often adopt a prophylactic approach and over-apply P fertilizers. The largest rates of fertilizer P application have been by farmers in East Asia, Western Europe, the mid-western United States, and southern Brazil. Depending on the soil type, its physical condition and chemical status, crop, and environmental conditions, 10–20% only of the fertilizer P applied in the first year is utilized by the crops; the remaining P adds to the soil reserves leading to its accumulation in slowly available P soil pools (Fig. 3). For example, from 1965 to 2007 cumulative P input of 1115 kg ha^{-1} in cropland in Europe from fertilizers and manures was more than three times the cumulative P removal by crops (Sattari et al., 2012). This 'residual' or 'legacy' P represents not only a significant environmental risk in terms of P-related eutrophication of rivers, lakes, and estuaries but is also a P reserve that can potentially be exploited to reduce fertilizer P use if appropriate technological and management interventions are developed and used.

Potassium

Potassium fertilizers are applied to most agricultural soils because most soil K (10 to 20 g kg^{-1} soil) is only potentially available for plant uptake. In terms of plant availability and complex dynamics in the soil, K can be differentiated into four soil pools: water-soluble or soil solution K, exchangeable K, non-exchangeable K, and structural K. There are dynamic equilibrium reactions between these pools. Plants and microbes take up K from the water-soluble pool (0.1–0.2% of total soil K), but the exchangeable K (1–2% of total soil K), which is electrostatically bound on the surfaces of clay minerals and humic substances, can be released quickly into the soil solution. Non-exchangeable and structural K (incorporated in the crystal lattice structure of minerals) account for 96–99% of total soil K, and are considered to be slowly- and potentially-available K sources for plants, respectively.

Removal of K by crops and losses by leaching in coarse-textured soils and soil erosion are not being adequately replaced. Less than 10% of K removed from the soil is counterbalanced by fertilizer K and other inputs. Application of less than the required amount of fertilizer K can lead to unbalanced fertilization and may also result in significant depletion of soil K reserves and reduced soil fertility. Application of K immediately leads to an increase in concentrations of soil solution K and to adsorption of K onto clay minerals as exchangeable K. Therefore, one application of fertilizer K to crops is generally sufficient to meet their requirement; only in coarse-textured soils with low cation exchange capacity (CEC) does it need to be applied in two or three split doses. However, irrespective of the cropping system, less fertilizer K applied than the crop requirement will compromise soil fertility and crop production. Nevertheless, rates of fertilizer K application are often based on optimal rates of fertilizer N rather than the crop's actual K requirements.

Micronutrients

Micronutrient deficiencies have increased markedly since the middle of the 20th century largely due to the intensification of arable farming, increased use of N, P and K fertilizers, cultivation of marginal and reclaimed land, loss of topsoil by erosion, liming of acid soils, and decreasing use of organic manures. While deficiency of Zn has emerged as the most ubiquitous micronutrient problem, B deficiency is the second most widespread. Deficiencies of Fe, Cu, Mn and Mo vary in importance in different regions of the world depending upon crop and soil properties. Regular use of micronutrient fertilizers is increasing both as soil applications (Zn, B, Cu and Mo), foliar sprays (Fe and Mn) or seed treatment (Mo). Simple compounds such as zinc sulphate, sodium borate, and copper sulphate are generally used for soil application.

Application of micronutrients to soils increases production of both above- and below-ground crop biomass, which leads to the accumulation of SOM. Additional SOM not only contributes to soil health, but also determines the distribution of micronutrients between soil colloids and solution by controlling sorption of micronutrients through active functional groups and by forming soluble complexes. The formation of stable micronutrient complexes facilitates uptake of micronutrients by plants (Dhaliwal et al., 2019). Since Zn, Cu, B and Mo are relatively less sensitive than Fe and Mn to redox changes in the soil, their availability to plants is more governed by SOM.

Effect of fertilizer application on soil organic matter

Soil organic matter regulates a host of biological, chemical, and physical soil processes and contributes to soil functions. Although the relative importance of many functions performed by SOM differs with soil type, climate, and land use, one of the most important is as a nutrient reservoir for plants and ultimately for animals and humans. Organic matter content of agricultural soils is a key indicator of soil health. If its content declines because of microbial mineralization and topsoil erosion, soil quality deteriorates, the benefits of SOM decline and there are adverse effects on N nutrition of crop plants. Because of the fundamental coupling of microbial carbon (C) and N cycling and the close correlation between the mineralization of C and N, SOM acts not only as the largest source of N for plants but also the largest sink for applied fertilizer N in agroecosystems.

Application of fertilizers, particularly N, to crops can result in the accumulation or decline of SOM. When applied as the crop demands, fertilizer N promotes the production of both above- and below-ground plant biomass which increases SOM contents. Excessive applications of fertilizer N may, however, accelerate SOM loss through microbial decay of plant litter and organic C already present in the soil. The accumulation of SOM from fertilizer use in cropping systems is widely accepted, but its loss because of excessive fertilizer N application has been demonstrated only recently by Poffenbarger et al. (2017). In continuous maize cropping for 16 years, SOM storage in the surface soil layer increased with increasing application of N, reaching a maximum at the recommended amount for maize. Application of less than the recommended N stimulated crop growth resulting in increasing crop residue inputs into the soil, which in turn increased the rate of SOM accumulation. On the other hand, application of fertilizer N to maize above the recommended rate did not increase crop biomass production significantly above that of the recommended level. Increased amounts of residual inorganic N in the soil from excessive fertilizer N stimulated the mineralization of SOM resulting in its net loss. Fig. 4 provides a conceptual depiction of the response of SOM as a function of fertilizer N application up to and beyond the recommended level. Considerable residual inorganic N resulting from excessive fertilizer N applications accelerates the mineralization of SOM by supplying N for the growth of microbes involved in this process. Application of fertilizer N at large rates also reduces the C:N ratio of crop residues, which accelerates their decay. Thus the response of SOM to fertilizer N is controlled by multiple processes but the extent of C immobilization or SOM mineralization is determined by the rate of fertilizer N application.

Increases in SOM and associated soil quality properties through the application of recommended levels of N, P, and K fertilizers in intensively managed multiple cropping systems have been recorded by several researchers cited by Bijay-Singh (2018). Table 1 gives the average increase in soil organic C (SOC) with fertilizer use estimated by four meta-analyses based on different crops and cropping systems in various regions of the world. Although Ladha et al. (2011) observed an average increase of 8% in SOC with fertilizer N use compared with that in no-N plots, the extent of increase in tropical, humid subtropical, and temperate soils ranged from 3 to 16%. The positive effect of fertilizer use on SOM in tropical soils was greater than that in temperate regions probably because tropical soils inherently contain small amounts of SOM. It is interesting to note that increases in SOM with fertilizer use have been observed in tilled soils under crop rotations. Tillage enhances the decomposition of organic matter in most soils. Therefore, the positive effect of fertilizer use on increasing SOM can be assumed to be higher than that shown in Table 1, and interpreting the changes in SOM with fertilizer use in long-term experiments needs to consider the interactions between tillage and fertilizer use.

In a meta-analysis of experiments in which soil C was isotopically labeled to distinguish between old and new SOM, it was found that N application substantially increased new soil C stocks (Huang et al., 2020). The N-induced increases were greatest in ecosystems receiving small amounts of N; however, the positive effects are likely to diminish with continuous N enrichment. In soils with poor mineral N supply, soil microbes fulfil their N demands by accelerating the decomposition of organic matter. Recently, Li et al. (2017) reported that application of recommended amounts of fertilizer N in soils with low N content reduced the decomposition of SOM already in the soil. Cultivation invariably reduces SOM, but the application of fertilizers reduces the extent of this decline.

Fig. 4 Conceptual diagram depicting effects of fertilizer N application to crops at below- and above-recommended rates on soil organic matter through relationships between increasing fertilizer N levels and yield and crop residue production, N use efficiency (N output per unit of N input), and residual soil inorganic N. Expected effects of fertilizer N application at below- and above-optimum levels on soil organic matter responses are shown above the light and dark green areas of the plots. Modified from Poffenbarger HJ, Barker DW, Helmers MJ et al. (2017) Maximum soil organic carbon storage in Midwest US cropping systems when crops are optimally nitrogen-fertilized. *PLoS One* 12: e0172293. doi: 10.1371/journal.pone.0172293.

Fertilizer use and soil acidification

Microbial nitrification of NH_4^+ ions and leaching of NO_3^- ions constitute the two processes that produce H^+ ions when N fertilizers are applied to the soil (Fig. 5). Uptake of NO_3^- ions by crop plants releases OH^- ions, which neutralize a portion of H^+ ions released during nitrification and nitrate leaching. If plants take up all the NO_3^- ions produced from urea and ammonium fertilizers, net H^+ ion production is zero. It implies that N fertilizers mostly lead to soil acidification if application rates exceed crop demands. Nevertheless, when NO_3^- ions are leached, they carry with them positively charged basic cations Ca^{+2} , K^+ , Mg^{+2} , and Na^+ , which accelerates soil acidification (Fig. 5). If the N fertilizer applied is ammonium sulfate, leaching of both NO_3^- and SO_4^{+2} ions deplete basic cations resulting in increased acidification. Urea is less acidifying than NH_4^+ -based fertilizers because OH^- ions produced during urea hydrolysis and ammonification neutralize a portion of H^+ ions produced from the nitrification of NH_4^+ ions.

Fig. 5 Schematic diagram showing soil acidification from the application of different nitrogen fertilizers for crop production. DAP: Diammonium phosphate, MAP: Monoammonium phosphate, AS: Ammonium sulfate, CAN: Calcium ammonium nitrate.

Dissolution of monocalcium phosphate, the P carrying compound in superphosphate fertilizer, in the soil results in the formation of dicalcium phosphate and phosphoric acid around the fertilizer granules. Subsequently, phosphoric acid is dissociated into H_2PO_4^- and H^+ ions. However, acidification of the soil with the application of superphosphate is mild because a portion of H^+ ions is neutralized by OH^- ions released during adsorption of H_2PO_4^- onto soil particles. Because H_2PO_4^- ions are strongly adsorbed onto soil particles, H_2PO_4^- -induced leaching of basic cations hardly occurs.

Buffering capacity of the soil to resist changes in pH constitutes one of the most important factors that determine the extent of soil acidification. Soil constituents such as calcium carbonate (in calcareous soils), organic matter, and Fe and Al (aluminium) oxides contribute to the pH buffering capacity of soils. Calcareous soils in semi-arid and arid regions of the world are highly buffered. Soils in temperate regions are generally neutral or slightly acidic. However, highly weathered soils in the tropics are mostly acidic and possess little or no pH buffering capacity. With the continuous use of fertilizer N in such poorly buffered soils, when base cations such as Ca^{+2} and Mg^{+2} are depleted during the acidification process, Al^{+3} is released from soil minerals, often reaching toxic levels. Toxic levels of Al in the soil solution affect root cell division and inhibit root elongation. Aluminium also reacts with P, reduces its solubility in the soil and creates P deficiency in plants.

Guo et al. (2010) noted that large rates of fertilizer N application in a major crop-production area in China between the 1980s and 2000s resulted in severe soil acidification. Based on paired data from 154 field locations, the average pH declined by 0.50 units in the topsoil. Transformations of fertilizer N in the soil released 20 to 221 kilomoles H^+ ha^{-1} year^{-1} in four different cropping systems. Uptake of base cations contributed a further 15 to 20 kilomoles H^+ ha^{-1} year^{-1} to soil acidification. A meta-analysis of 106 studies from all over the world revealed that on average soil pH declined by 0.26 units from N additions and the rate of decline was linearly related to rates of N application (Tian and Niu, 2015). When the duration of the experiment was longer than 20 years, the extent of soil acidification due to N application was less. In the early stages of significant N additions, base cations Ca^{+2} , Mg^{+2} , and K^+ play a crucial role in buffering against N-induced soil acidification, but in many regions of the world, N additions are now transitioning to the Al^{+3} -based buffering phase.

Effect of fertilizers on soil microbial biomass

Microorganisms play an important role in maintaining soil fertility and productivity. The impact of fertilizers on different assemblages of soil microorganisms can have important implications for sustainable agriculture. Mineral fertilizers interact with microbial communities in the soil and affect biological activity, soil bacterial biomass, and community composition through enhanced cropping system productivity, crop residue return, SOM accumulation, and increased nutrient availability. Fertilizers also affect microbial life in the soil indirectly by altering pH. Soil acidification caused by the application of N fertilizers can have a considerable negative effect on soil organisms. Large amounts of nutrients from excessive applications of fertilizers may also decrease soil microbial activities.

Positive or negative effects of fertilizer use in crop production on the soil biota are determined by the type and amount of fertilizer used, the mode of application and duration. For example, the potential negative effect of a large concentration of ammonia fertilizer applied in bands on soil microbial life is usually short-term and confined to the application zones. Fertilizer application to crops usually increases soil microbial biomass. Several studies have reported a significant increase of soil microbial biomass, rates of microbial respiration, and community functional diversity with the long-term use of mineral fertilizers in cropping systems (Bijay-Singh, 2018). In some studies, the application of P together with N further stimulated soil microbial biomass. A significant correlation between microbial properties and SOM content suggests that the application of mineral fertilizers positively influences microbial life in the soil indirectly through the accumulation of SOM. In general, microbial activity in the soil is primarily limited by the availability of C substrate. But in agroecosystems when demand for N exceeds its supply, fertilizer N may exert a positive effect on soil microbial activity although there might be a negative impact from associated reduced pH. In two global meta-analyses from 55 studies on lowland rice (Geisseler et al., 2017) and 64 studies on upland crops (Geisseler and Scow, 2014), the application of mineral fertilizers (N or NPK) resulted in an overall increase of 15–29% in microbial biomass C compared to the no-fertilizer control treatments (Table 2). In upland crops, the increase in microbial biomass C averaged 48% in soils with pH 7 or higher but a decrease was observed with a pH below 5. When the duration of the experiment was less than 10 years, an average decrease of 22.7%

Table 1 The extent of increases in average soil organic C content with the application of fertilizer N compared to unfertilized controls in meta-analyses of long-term fertilizer experiments under different cropping systems in different regions of the world.

Crops	Region	Duration of long-term experiments	Number of experiments/ observations	Percent increase in soil organic C	References
Non-lowland rice crops	World	5–130 years	64	12.8	Geisseler and Scow (2014)
Cereal crops	World	6–158 years	104	8	Ladha et al. (2011)
Wheat, barley, oats, sugar beets, potato, maize, sorghum, rye	Europe	16–108 years	20	10	Körshens et al. (2013)
Irrigated or rainfed lowland rice	Asia	10 weeks– 58 years	46	13.4	Geisseler et al. (2017)

Table 2 The average response of soil microbial biomass carbon (MBC) to the application of mineral fertilizers (N or NPK) in meta-analyses conducted on experiments on lowland and non-lowland rice.

Experiments and treatments	Number of data sets	Percent change in MBC in +N treatments over no-N control
Non-lowland rice crops experiments (Geisseler and Scow, 2014)		
All data sets	107	+15.1
pH in +N treatment: <5	17	-3.1
pH in +N treatment: 5-7	39	+9.3
pH in +N treatment: >7	17	+48.2
Duration of experiment: 5-10 years	18	-22.7
Duration of experiment: 10-20 years	34	+17.2
Duration of experiment: longer than 20 years	55	+30.5
Lowland rice experiments (Geisseler et al., 2017) ^a		
Mineral N	19	+21.0
Mineral NPK	48	+29.0

^aNeither the duration of the experiment nor the annual rate of fertilizer N application influenced the response of MBC to mineral fertilizer N application.

in microbial biomass C was observed because of fertilizer N application. However, in experiments longer than 10 years, a large positive effect of fertilizer use on microbial biomass C was recorded (Table 2). In soils under lowland rice, the duration of the experiment or fertilizer N rate (40–830 kg N ha⁻¹) did not influence the effect of fertilizer use on microbial biomass C.

Long-term use of mineral fertilizers in agro-ecosystems affects the soil microbial biomass, but there are conflicting reports about its influence on the composition of the bacterial community. Guo et al. (2019) did not observe a significant effect of NPK fertilizer application on microbial communities. Some studies also reported that functional diversity, prokaryote and fungal taxonomic diversity were not significantly different between NPK treated plots and no-fertilizer plots. Zhang et al. (2017) studied the effects of fertilizer NPK applications on bacterial diversity and community structure in acidic (pH 5.8), near-neutral (pH 6.8), and alkaline (pH 8.4) soils and found that they did not affect operational taxonomic unit richness or the Shannon diversity index in the alkaline soil. In contrast, both microbiological diversity indices were significantly lower under fertilizer NPK application in acidic and near-neutral soils. In general, greater abundance and diversity of soil micro- and macro-organisms in optimally fertilized fields can be attributed to the accumulation of crop biomass/organic matter in the topsoil, regulation of soil moisture and temperature, and enhanced growth of roots and consequent distribution of root litter and rhizosphere exudates.

Over-use of mineral fertilizers in cropping systems can potentially damage habitats of biological communities and disrupt their functions. Treseder (2008) conducted a meta-analysis of 82 published studies and found that the average decline of microbial biomass under conventional rates of fertilizer N application was 15.4%. In studies that examined different groups of microbes separately, fungi and bacteria were not significantly altered. However, declines in the abundance of microbes as well as fungi were observed in studies with longer duration of fertilizer N over-use.

Effect of fertilizer use on enzyme activity in soil

Microorganisms in the soil synthesize and secrete extracellular enzymes, which contribute to forming and decomposing organic materials. Soil enzymes are sensitive indicators of soil fertility and productivity. Hydrolases are important soil enzymes because of their role in acquiring C, N, and P during primary metabolism. Oxidoreductases facilitate SOM decomposition. The release of biologically available nutrients from organic compounds is controlled by β -1,4-glucosidase (β G), β -1,4-N-acetylglucosaminidase (NAG), leucine aminopeptidase, and acid phosphatase (AP). The intensity and direction of different biochemical processes in the soil can be gauged from enzyme activities involved in the various processes. Microbial demand for nutrients and the response of agroecosystems to environmental changes are also reflected in extracellular enzyme activities.

A meta-analysis based on 107 datasets from 64 non-lowland rice long-term experiments from around the world (Geisseler and Scow, 2014) revealed that activities of protease, urease, and phosphatase were not significantly affected by N fertilization. Phosphatase activity was strongly inhibited by P fertilization. Another meta-analysis based on 64 studies conducted by Chen et al. (2018) showed that N fertilizer application increased the activities of NAG and urease enzymes by 5.5 and 11.6%, respectively. The activity of glycine aminopeptidase was reduced by 33% but no response was observed for the non-specific protease and leucine aminopeptidase. Jian et al. (2016) conducted a meta-analysis of 65 published studies and reported that N fertilizer application in agricultural soils significantly increased β -D-cellobiosidase, hydrolytic C acquisition enzymes, AP, β -1,4-xylosidase, β G, α -1,4-glucosidase, and urease activities by 6.4, 9.1, 10.6, 11.0, 11.2, 12.0, and 18.6%, but decreased peroxidase, oxidative decomposition and phenol oxidase by 6.1, 7.9 and 11.1%, respectively. The effect of fertilizer N on enzyme activities does not show a simple increasing or decreasing trend because the effect varies with soil type, composition of the soil microbial community, and the kind of enzyme reaction. Mineral fertilizers, particularly N, may also indirectly affect activities of soil enzymes through their effect on soil properties like pH.

Fertilizer effects on soil erodibility

Soil erodibility is defined as the susceptibility of soil particles to be detached and become available for erosion by wind, water, or ice. Soil erosion tends to increase with decreased ground cover. Ground cover protects soils from the impact of rainfall and wind, and can also buffer these impacts on soils with weak aggregate stability resulting from low SOM contents. Fertilizer use on farms does not directly influence soil erodibility, but it improves crop cover and aggregate stability through the accumulation of SOM. Under a well-developed crop canopy rainwater is held in the canopy reducing the risk of runoff and soil erosion. In well-fertilized fields, soil also tends to remain in place because of a more extensive root system. For example, in fields with a 2% slope, soil erosion was reduced by more than 9% in the fertilized fields compared to the controls (Bhattacharyya et al., 2015). In studies conducted in seven countries in Asia by the International Board for Soil Research and Management, soil erosion was reduced from 50 to 15 t ha⁻¹ year⁻¹ in the cropped fields with fertilizer application.

Soil physical properties as influenced by fertilizer use

Fertilizers affect soil physical properties primarily by increasing the production of the above-ground and root biomass. The incorporation of organic matter into the soil through crop residues and root biomass leads to improvement in soil structure and water retention capacity, increased infiltration rate, and reduced bulk density. Increased stability of aggregates and soil porosity results in an improved root environment and an increased percentage of macro-aggregates adds to the protection of C and N in the soil.

The use of fertilizers can also change soil physical properties independently of the SOM. Pernes-Debuyser and Tessier (2004) observed that in uncultivated plots to which various fertilizer treatments were applied each year for 70 years, the same small SOM content was recorded but the soil physico-chemical environment and soil physical properties differed strongly among plots. By reducing soil pH and CEC, long-term use of NH₄⁺ fertilizers resulted in degradation of hydraulic properties of the soil. On the other hand, amendments supplying bases such as CO₃²⁻, OH⁻, O²⁻ increased soil pH and CEC as well as its saturation with calcium, which improved soil structural cohesion and water flow properties.

Pore geometry of the soil is modified by fertilizer-induced increased rooting depth and root proliferation in field crops. It affects water transmission characteristics of the soil profile as well as the volume of soil exploited by the roots for water and nutrients. Schjonning et al. (2005) observed that while long-term application of fertilizers and organic manures did not affect soil hydraulic conductivity in the plough layer of a sandy loam soil, improved root growth conditions resulted in increased macro-porosity in the subsoil and near-saturated conductivity for water.

Fertilizers and heavy metal contamination of soils

As P fertilizers are produced from phosphate rock, these can contain substantial amounts of impurities such as cadmium (Cd), lead (Pb), chromium (Cr) and some radionuclides such as uranium (U), thorium (Th), and polonium (Po). There is a wide variation in the heavy metal content of rock phosphates mined in different regions of the world and this is reflected in the P fertilizers produced. Accumulation of heavy metals in the soil adversely affects not only its biological characteristics, but a decrease of soil pH with repeated applications of N and P fertilizers may also facilitate the uptake of heavy metals by plants leading to their entry into the animal and human food chain. The elements applied to soil from P fertilizers mainly accumulate in the surface layer of the soil in bioavailable forms. In acidic soils with coarser textures, such elements are more available than in alkaline soils and those containing large amounts of clay.

Among the heavy metal contaminants in P fertilizers, Cd has received the most attention because of its adverse effects on human health. Depending on the source, single superphosphate can contain between 2 and 40 mg kg⁻¹ Cd; the range in triple superphosphate can be from <10 to >100 mg kg⁻¹ Cd. In most arable soils, P fertilizers constitute the main source of Cd. Several studies have reported a gradual accumulation of heavy metals and Cd in agricultural soils from repeated applications of P fertilizers (Khan et al., 2018). Surveys show that Cd concentrations in topsoils follow the pattern of distribution of fertilizer P applications. Khan et al. (2018) also summarized research reporting increases in radionuclides in soils from long-term P applications. However, there is insufficient evidence for potential long-term effects of P fertilizer use on radiobiological exposure.

If P is applied through ammonium-containing fertilizers such as diammonium phosphate and monoammonium phosphate to neutral or alkaline soils, in which substantial leaching of nitrate-N occurs, the resulting temporary soil acidification of the rhizosphere will mobilize both phosphate and Cd. In contrast, if P is repeatedly supplied to crops through single or triple superphosphate, the induced changes in soil pH will transform Cd into less bioavailable compounds such as cadmium phosphate.

Microbial biomass and enzyme activity in the soil are important indicators for the extent of soil contamination with heavy metals such as Cd and Pb. Significant inhibition of microbial activity in soils contaminated with heavy metals has been reported in several studies. In a meta-analysis based on 671 observations, Aponte et al. (2020) found the activities of arylsulfatase, dehydrogenase, β -glucosidase, urease, acid phosphatase, alkaline phosphatase and catalase were linearly reduced in response to soil contamination with Pb, Zn, Cd and Cu.

Effects of fertilizer use on pollution of surface and ground waters, and climate change

With fertilizer N consumption in East and South Asia surpassing that in North America and Europe (Fig. 1), nitrate pollution of freshwaters and emission of nitrous oxide (N_2O), a long-lived greenhouse gas that accumulates in the atmosphere and contributes to climate change and stratospheric ozone depletion, are now becoming pervasive global problems. The present trends of nitrate-N enrichment of groundwater reflect the legacies of current and past applications of N fertilizers and manures. In addition to the rates of fertilizer N use, factors such as the extent of irrigated area, and annual mean temperature determine the spatial and temporal distribution of nitrate-N in groundwater beneath cropland. Depending upon fertilizer rate, soil nitrate leaching varies from 10 to 30%. One of the most comprehensive assessments of N_2O emissions by Tian et al. (2020) revealed that 43% of the global emissions during 2007–2016 ($7.3 \text{ Tg N year}^{-1}$) were from anthropogenic sources. Direct emissions from N application in agriculture contributed to 52% of emissions linked with anthropogenic activities. Furthermore, up to 71% of the increase in anthropogenic N_2O emissions from the 1980s to 2007–2016 was due to direct emissions from fertilizer applications in agriculture. Important strategies to control nitrate leaching and N_2O emissions from cropland include application of fertilizer N as needed by the crop and synchronizing the time of its application with the pattern of N uptake by crops and irrigation management.

Both N and P contribute to eutrophication, but the main focus has been on P because a single atom of P is required to produce as much phytomass as 16 atoms of N and 106 atoms of C. Even relatively small losses of P from agriculture to surface water bodies may contribute to eutrophication. With the continued application of P in fertilizers and manures to soils under intensive agriculture, there is surplus P in the soil. Although applied P is strongly bonded with soil components and the release of P to the soil solution or runoff water depends on soil type, surplus P in the soil remains the principal cause of its transfer to surface water bodies. Phosphorus in streams and lakes is also delivered through erosion of P fertilized soil. Application of fertilizer P based on soil tests is the best way to reduce the contribution of fertilizers to eutrophication. Omitting P application for some years on soils with a large P content without affecting yield can also be effective. Other measures are maintenance of proper soil pH, incorporation of fertilizer P rather than broadcasting, and proper timing of fertilizer application (Smil, 2000).

Balanced application of fertilizer nutrients and soil properties

Nutrient imbalances in the soil resulting from the application of N, P, and K through fertilizer rates lower or higher than those recommended for a crop can prove deleterious for many soil functions. The adverse effect of imbalanced use of fertilizer N, P, and K on the performance of different crops and cropping systems is well proven. Long-term experiments, in which N, P and K were applied in combination according to soil test results and crop demands led to a greater accumulation of SOM compared to controls where only one or two of the three plant nutrients were applied (Bijay-Singh, 2018). Increases in both SOM and biomass C with balanced nutrient application result from larger root and above-ground crop biomass production. Increased soil microbial functional diversity has also been observed in long-term balanced fertilization experiments. Balanced application of fertilizer N, P, and K can sustain bacterial and archaeal abundances, and bacterial community structure, which contribute to soil fertility. Based on measurements of soil organic C, total N, available P, pH, basic cations, microbial biomass C, microbial biomass size, and crop yield, Belay et al. (2002) inferred that judicious and balanced application of mineral fertilizers can maintain soil productivity and soil quality in the long-term.

Soil properties under integrated nutrient management based on mineral fertilizers and organic manures

Integrated management of mineral fertilizers and organic manures has evolved as an approach to achieve sustainable crop production while ensuring maintenance/improvement of soil fertility and soil health. It is an ecologically sound and economically optimized nutrient management system based on using all possible organic and inorganic nutrient sources in an efficient and integrated manner. Application of organic nutrient sources together with fertilizers, affects soil properties differently from fertilization based only on mineral fertilizers. In general, optimal use of organic and inorganic sources of plant nutrients always leads to improvement in the soil environment for plant growth. Application of organic sources results in the accumulation of SOM which improves physical, chemical and biological properties of the soil. It is not only the nutrients supplied by organic sources but also the other benefits of SOM enrichment that increase crop yields under integrated nutrient management.

Several studies with different crops, particularly from China and India, have reported increased SOM with the application of organic manures together with fertilizers compared to only fertilizer use. Organic sources of nutrients supply C-rich organic compounds to generally C-limited microbial communities in arable soils. Therefore, integrated nutrient management leads to increased soil microbial biomass and enzyme activities in the soil. A meta-analysis of studies conducted on rice and wheat from 1989 to 2016 in South Asia revealed that integrated nutrient management increased average soil organic C by 23.2% in rice and 16.2% in wheat compared with mineral fertilizers (Sharma et al., 2019). The increases in soil organic C were 26.5% in loamy soils and 12.3% in clayey soils. Furthermore, total N, available P, available K, and soil microbial biomass C were positively influenced by integrated nutrient management. In a meta-analysis of 58 long-term experiments in China, Waqas et al. (2020) inferred that the accumulation of soil organic C was greater when organic manures were integrated with balanced and recommended applications of

fertilizer N, P, and K rather than with their unbalanced use. In a study based on 80 long-term experiments in Europe, [Zavattaro et al. \(2017\)](#) reported that application of bovine farmyard manure and bovine liquid slurry in combination with mineral fertilizers increased SOC, respectively by 33.4% ($n = 54$) and 17.3% ($n = 10$) over mineral fertilizer treatment at a similar N rate. Corresponding increases in soil organic N content were 22.4% ($n = 17$) and 15.5% ($n = 11$).

Summary

In the imminent future, mankind will continue to depend upon agriculture and agriculture will continue to depend upon mineral fertilizers. However, mineral fertilizers are chemicals that can potentially alter and sometimes cause irrevocable changes in soil characteristics and may affect normal functioning of the soil. To reduce the risk of reduced yields because of nutrient deficiencies, farmers sometimes apply fertilizers in amounts that are greater than necessary, and effects on soils may be adverse. A major portion of applied fertilizer N converts into organic forms to become a part of SOM and adds to the soil N pool. Depending upon the crop, climate and soil conditions, a substantial amount of N taken up by crop plants is met from the N mineralized from the soil N pool that has been enriched by fertilizer N applications in previous years. The major portion of P applied as water-soluble fertilizers is distributed between the readily- and less readily-available P pools in the soil. Fertilizer K when applied to the soil immediately leads to an increase in K in the soil solution, but most is adsorbed on clay minerals as exchangeable K.

Application of recommended rates of fertilizers to crops promotes increases in both above- and below-ground plant biomass leading to increased organic matter content in the soil. However, excessive use of fertilizer N may accelerate microbial decay of plant litter and organic matter already present in the soil. Application of N fertilizers leads to soil acidification through microbial nitrification of ammonium ions and leaching of nitrate ions from the soil. Although urea is less acidifying than NH_4^+ -based fertilizers because OH^- ions are produced during urea hydrolysis, buffering capacity of the soil to resist changes in pH determines the extent of soil acidification. The application of mineral fertilizers in general positively influences microbial life in the soil, although soil acidification from the use of N fertilizers can have a considerable negative effect on soil organisms.

Through improved crop cover, development of an extensive root system, and increased aggregate stability with SOM accumulation, fertilizer use on farms can reduce soil erodibility. Fertilizer use also improves various soil physical properties and water transmission characteristics of the soil profile. Heavy metals and radionuclides contained as impurities in P fertilizers may contaminate soils. Pollution of groundwater due to nitrate leaching beneath agricultural lands, emission of N_2O , and loss of P from fertilized soils by runoff leading to eutrophication may happen when fertilizers are not managed efficiently. Balanced application of N, P, and K and integrated management of mineral fertilizers with organic manures generally enhance the accumulation of soil organic matter and biological properties of the soil.

Enhancing fertilizer use efficiency is going to be one of the biggest challenges in future agriculture. With increasing fertilizer prices, improved nutrient management will ensure that sustainable and economic food production is achieved without excessive use of fertilizers. Reduced fertilizer application will result in healthy soils with minimal risks of environmental pollution and climate change associated with fertilizer use. The continuous increase in the price of fertilizer nutrients from increasing costs of energy, mining, storage and transport, and declining accessibility of phosphate rock reserves also require efficient and effective fertilizer management. The sustainable and efficient management of fertilizers will be beneficial for the economy, for human health and for the environment.

Abstract

Leaves are protected by the cuticle, stomata and other epidermal structures against the uncontrolled exchange of matter with the environment. Nevertheless, solutes such as mineral fertilizers, biostimulants or pesticides may penetrate the external plant surface. Meanwhile, foliar application of plant nutrients is a common agricultural practice, especially for micronutrients. This chapter summarizes the current knowledge about the barrier properties of both the cuticle and stomata against the penetration of solutes. Practical aspects of foliar fertilization are outlined.

Glossary

Adjuvant Multifunctional and heterogeneous chemicals which may improve spray formulation performance.
Cell wall Hydrated extracellular material made of polysaccharide polymers which surrounds plant cells.
Cuticle Lipidized part of the epidermal cell wall of at least aerial plant organs.
Deliquescence For a certain temperature, relative humidity at or above which solid salt particles begin to become a liquid.
Efflorescence For a certain temperature, relative humidity at or below which a highly concentrated solution begins to crystallize.
Partition coefficient Estimate of the degree of lipophilicity or hydrophilicity of a substance.
Stomata Micrometric size pores in the leaf surface controlling gas exchange.
Trichomes Epidermal cells which grow outwards and may be glandular or not, single celled or multicellular.

Key points

- Plant leaves can absorb solutes such as mineral nutrients and agrochemicals.
- The penetration of leaf surfaces is a passive process.
- Nutrients enter leaves by diffusion.
- Nutrients can be taken up both through the cuticle and through stomata.
- Air humidity is decisive for the rate of foliar absorption.

- Foliar uptake can be fast and efficient.
- Foliar fertilization is of particular importance for micronutrients and calcium.
- Uptake can be improved by adding adjuvants to the foliar formulations.
- Leaf burn can be the result of inadequate application of foliar fertilizers.

Introduction

Under natural conditions plants absorb water and mineral nutrients with their roots. In agriculture, however, foliar nutrient application is a common practice to complement root fertilization, particularly when nutrient availability in soil is limited and nutrients have to be supplied quickly (Eichert and Fernández, 2012). Since most foliar fertilizers can be mixed with pesticides in the sprayer tank, foliar fertilization is often part of routine cultural practices in commercial agriculture.

Foliar application is often preferred to the application of fertilizer to soil when constraints such as soil pH or calcium carbonate limit the availability of nutrients such as zinc (Zn), iron (Fe), and manganese (Mn) or when deep-rooted perennial plants are grown in soils which tend to immobilize nutrients such as potassium (K). The addition of Fe salts to an alkaline or calcareous soil is usually ineffective because soil mineral Fe (often Fe oxides) is poorly available at high pH.

There are several situations in which foliar nutrition can effectively replace or complement (Table 1) soil fertilization. The amount of nutrients that can be supplied through the leaves is limited because above a certain threshold concentration foliar sprays can be toxic. Foliar fertilizer application can meet plant nutrient demand if the requirement for a given nutrient is low, which is the case for microelements (boron (B), copper (Cu), Fe, Mn, molybdenum (Mo), and Zn) or when soils already have adequate fertility, so that only small additional amounts are needed. Multiple foliar applications may be needed to ensure adequate nutrient delivery.

Because of the usually high efficiency of foliar fertilization, this practice is regarded as a promising technique in reducing the amount of chemicals in the environment, thereby promoting sustainable agriculture. While roots are organs specialized in nutrient absorption and root uptake is therefore more or less under physiological control, nutrient uptake by leaves is not. The penetration of leaf surfaces is a passive physical process governed by the laws of diffusion. Therefore, both properties of the applied nutrient solution (e.g., concentration and solubility of the nutrient) and of the leaf surface (e.g., permeability and wettability) affect the uptake process. Several variables influence the effectiveness of foliar-applied fertilizers and may explain the often-reported inconsistency in plant response to foliar nutrition.

Barrier properties of leaf surfaces

To minimize uncontrolled exchange of matter with the environment, leaf surfaces of terrestrial plants are covered with a cuticle. In general, the cuticle can be considered a non-living, hydrophobic skin with low permeability for water, gases and solutes such as mineral fertilizers. To enable CO₂ (carbon dioxide) uptake required for photosynthesis, leaves are equipped with stomata as adjustable apertures occurring in the leaf surface, which optimize the trade-off between CO₂ uptake and water loss. The evolutionary development of the cuticle and stomata as barriers against the uncontrolled exchange of matter was the prerequisite for colonization of the land surface by higher plants, but these barriers do not fully impede the penetration of dissolved nutrients into the leaves. This enables the supply of mineral nutrients to plants by foliar sprays as an alternative or supplement to soil application.

Table 1 Major agronomic and physiology-related conditions promoting the effectiveness of foliar nutrient supply.

Objective	Example
Prevent or cure transient nutrient deficiency	When nutrient demand exceeds root uptake rate
Bypass soil conditions limiting nutrient availability or uptake and accelerate plant response	Unfavorable pH and conditions for root growth, including soil temperature, moisture, and aeration
Increase the buildup of nutrient reserves for storage and successive remobilization the following year	It applies to perennial plants and to nutrients that are phloem-mobile such as nitrogen
Cure or prevent nutrient deficiencies of specific organs that occur despite optimal root uptake due to problems in within-plant distribution of a given nutrient	It applies to nutrients such as Ca which move mainly through the transpiration stream toward the leaves, leading to calcium-related disorders in fruits, e.g., in apple and in tomato
Supply nutrients to plants with deep root systems when soil surface application of fertilizers is almost without effect	It applies to trees, especially for nutrients such as K, Ca, or Mg, whose penetration to root zone layer is sometimes difficult and in general to conditions of absence of irrigation or rain

Nutrient uptake through leaves

Foliar-applied nutrients may penetrate the leaf surfaces through the cuticle and stomata, and it is assumed that both pathways play an important role for the uptake of foliar-applied nutrients. Moreover, cuticle injuries caused by, for example mechanical stress caused by wind, may enable solute uptake. In contrast to root uptake, where physiological processes are involved, the penetration of leaf surfaces by solutes is a purely passive process driven by the concentration gradient between the surface and leaf interior. After penetration of the leaf surface, mineral nutrients will reach the interior of the plant and are thus protected from washing off by rain, for example, and may be utilized by the plant. However, to fulfill their physiological functions most elements have to be taken up into the leaf cells. This is the first point where the uptake process is under physiological control.

The cuticular and stomatal pathways differ fundamentally in their physico-chemical characteristics: The cuticle is solid and rather lipophilic, constituting an effective barrier for the diffusion of large and/or polar, hydrophilic molecules. Ions, in particular, which are the most common constituents of mineral fertilizers, are highly polar. Therefore, the cuticle represents a substantial barrier against the uptake of foliar fertilizers. By contrast, penetration of stomata is assumed to take place in thin water films covering the walls of the pores. Therefore, this absorption pathway can be more efficient for water soluble fertilizers. However, it was shown that this pathway is not present in all stomata, which may contribute to variable rates of uptake.

Fig. 1 summarizes the current view on uptake pathways for foliar applied substances with a special emphasis on water soluble solutes. At low external relative air humidity (RH) the cuticle is an effective barrier against the penetration of applied hydrophilic solutes. The hydrophobic properties of the cuticle prevail because only few water molecules are present (Fig. 1A). This changes at high RH or underneath a drop of aqueous solution. More water molecules are preferentially absorbed in the cuticle by hydrophilic cell wall constituents. Water clusters may form bridges between the leaf surface and leaf interior in which applied solutes may penetrate the cuticle (Fig. 1B). The surfaces of some stomatal pores may be coated by thin water films enabling the diffusion of solutes into the leaves (Fig. 1C).

Nutrient uptake through the cuticle

The surface of plants is covered with the cuticle, a non-living 'skin' protecting plants from excessive water loss by transpiration and uncontrolled exchange of solutes with the environment. The structure and composition of the cuticle vary greatly among plant species, varieties, organs and developmental stages (Fig. 2). The cuticle consists of cell wall material, cutin, a polymer forming a three-dimensional matrix in which waxes are embedded (intra-cuticular waxes), and waxes on the surface of the cuticle (epicuticular waxes). Waxes are predominantly apolar and thus make the cuticle and leaf surfaces rather hydrophobic. Variable amounts of polysaccharide fibrils and pectin lamellae may extend from the epidermal cell wall, binding the cuticle to the underlying tissue. In many plant species cell wall polysaccharides may extend to the outermost leaf surface. In contrast to waxes, polysaccharides are

Fig. 1 Pathways for the penetration of hydrophilic solutes across leaf surfaces. Water (black) may be present in the cuticle (A and B) or in some stomata (C), enabling the diffusion of hydrophilic solutes present on the leaf surface into the leaves (orange arrows). At low relative humidity (RH), water in the cuticle is present mostly in the inner regions adjacent to the epidermal cells, whereas in the outermost regions only little water is absorbed (A). Only if RH is high or underneath a drop of liquid water, the cuticle absorbs enough water from the outer side to create continuous aqueous connections crossing the cuticle (B). In some stomata, water clusters may be present and form thin water films creating diffusion pathways for the penetration of solutes by diffusion (C). Since RH within the stomatal pores is generally increased by transpiration, these stomatal water films may exist at lower external RH and in the absence of liquid water drops on the leaves.

Fig. 2 Topography (A–C) and cross sections of a cucumber leaf observed by scanning (A–C) and transmission (D and E) electron microscopy. Both the upper (A) and lower (B and C) sides are covered with a cuticle (Cu) and have trichomes (T). Many stomata (S) are present in the lower side (B and C). All epidermal cells including trichomes are surrounded by a cell wall (CW) and have a cuticle (Cu) at the surface (D and E). Stomata are formed by two guard cells (GC) surrounded by a cuticle and a cell wall (E).

hydrophilic and may therefore adsorb water molecules, a process which is thought to promote the formation of aqueous pores in the cuticle enabling the penetration of the cuticle by polar solutes (see below).

Cuticular penetration of lipophilic solutes

The more or less hydrophobic nature of the cuticle makes it an effective barrier against penetration by hydrophilic, polar solutes, such as mineral fertilizers. However, lipophilic molecules, such as certain pesticides, may penetrate cuticles at high rates. The penetration of cuticles by lipophilic molecules is described by the solution-diffusion model. According to this model, molecules have to dissolve in the cuticle before they cross the cuticle by diffusion. The rate of penetration of a molecule is a function of its solubility and mobility in the cuticle according to:

$$P = D \times K / \Delta x, \quad (1)$$

where P is the permeance (m s^{-1}), D ($\text{m}^2 \text{s}^{-1}$) is the diffusion coefficient in the cuticle, K is the partition coefficient of the molecule between the external solution and the cuticle as a measurement of solubility, and Δx (m) is the path length of diffusion. The solubility parameter K takes into account the chemical affinity between the permeating molecule and the cuticle, whereas the diffusion coefficient D is a function of the size of the molecule. Because diffusion takes place in the narrow voids in the cuticle, which have diameters in the order of 1–5 nm, the cuticle is highly size selective and larger molecules may be practically excluded from diffusion across it.

Cuticular penetration of hydrophilic solutes

With a few exceptions, such as boric acid or urea, foliar fertilizers are applied as ions, which are very polar and have a very low solubility in the cuticle. Applying the solution-diffusion model to these polar, hydrophilic substances results in extreme underestimation of the observed rates of penetration across the cuticle. Therefore, many researchers assume that hydrophilic solutes penetrate the cuticle by an alternative pathway called ‘polar pores’ or ‘aqueous pores’. It was suggested that these ‘pores’ are formed by clusters of water molecules adsorbed by the hydrophilic moieties of the cuticle, mainly by intra-cuticular cell wall material (Fernández et al., 2017, 2021). It has been observed that the rates of penetration of hydrophilic solutes increase with increasing air

Fig. 3 Model of the formation of aqueous connections ('pores') traversing the cuticle. In this simplified model, the cuticle (CU) consists of a matrix of cutin and embedded waxes (MX) interspersed with hydrophilic domains, mostly provided by polysaccharides (PS) and other hydrophilic constituents. The overlying layer of epicuticular waxes (EW) facing the outer side lacks polysaccharides. Water clusters (WC, black dots) are formed by adsorption of water by the hydrophilic domains. If air humidity is low, water clusters mainly originate from the epidermal cells underneath the cuticle (A). With increasing external air humidity, more water is absorbed by the cuticle from the outer surface (B). At high humidity tortuous connections between the leaf surface and the leaf interior emerge (C). Externally applied solutes may diffuse in these connections through the cuticle (orange arrow in C). For clarity, other water clusters in the cuticle adjacent to the depicted emerging connection are not shown.

humidity, and uptake increases markedly when the air approached saturation with water vapor. These observations gave rise to the 'dynamic pore model' of cuticular penetration of hydrophilic solutes depicted in Fig. 3.

According to this model, water is adsorbed by hydrophilic constituents of the cuticle and forms water clusters in the cuticle. In dry air, water clusters are practically restricted to the lower part of the cuticle where the epidermis provides a constant water source. Small amounts of water only will be absorbed by the outer cuticle, and hence less functional 'pores' traversing the cuticle will exist. With increasing air humidity, more water is absorbed by the cuticle eventually creating continuous connections between the leaf surface and the epidermis. The permeability of cuticles is thus not constant but depends on environmental conditions.

From an ecophysiological perspective, the variable permeability of the cuticle makes perfect sense: under dry conditions, the small water content of the cuticle minimizes the permeability of the cuticle, not only for solutes but also for water. Therefore, water loss by the plant is reduced. If air is saturated with water, transpiration ceases and the flow of water and solutes into leaves is interrupted. Under these conditions, many plants actively pump water from the roots to the leaves where drops of xylem sap are exuded on the tips or edges of leaves, a phenomenon called guttation. This occurs mainly when transpiration is suppressed and shows, that the cycling of water and nutrients in the plants through the xylem and phloem has to be sustained. The considerable water permeability of cuticles at high air humidity will facilitate transpiration, thereby sustaining water and nutrient transport in the xylem.

From a practical perspective, the variable permeability of cuticles has to be taken into account when applying foliar fertilizers or pesticides. The water absorption ('swelling') of the cuticle after longer periods of high air humidity or even rainfall increases rates of penetration. On the one hand, this may be beneficial when large rates of uptake have to be achieved. On the other hand, uptake rates higher than usual may pose the risk of leaf damage. In this case, application doses should be reduced accordingly.

Role of specific leaf structures

A range of studies showed that the cuticle covering leaf veins and trichomes may represent preferential uptake routes for nutrients applied to the leaves. It was shown that calcium (Ca) was preferentially absorbed by veins of beech leaves and that the cuticle above veins differed from the surrounding cuticle in structure and composition (Bahamonde et al., 2018). In sunflower leaves non-glandular trichomes are important entry sites for foliar-applied Zn. To date the reason for the higher cuticular permeability above these leaf structures and its ecological significance is not well understood.

Nutrient uptake through stomata

In terrestrial plants, the stomata are the sites of exchange of gases (mainly CO₂, O₂ (oxygen)) with the atmosphere. Their number per mm² of leaf surface varies between about 20 in succulents, 100–200 in most annual species, and more than 800 in certain tree species. In terrestrial plants, stomata are usually more abundant (most annual species) or confined (many tree species) to the lower (abaxial) leaf surface. By contrast, in leaves of aquatic plants like sacred lotus (*Nelumbo nucifera* Gaertn.) they may only occur on the upper side.

Stomata are required to enable photosynthesis. The cuticle itself can hardly be penetrated by gases like CO₂ which is required to convert solar energy into chemical energy (sugars). Therefore, stomata as 'holes' in the leaf surface are required. The aperture of stomata can be adjusted. When open they enable the uptake of CO₂ into leaves by diffusion. However, open stomata also inevitably enable the escape of H₂O (water) from the leaf interior. Thus, photosynthesis is always combined with water losses, which have to

be compensated for by water uptake from the soil. The rate of water loss by transpiration depends on environmental conditions, mainly on air humidity, temperature, and wind. When rates of water losses are too high, plants react by closing stomata.

At first sight, stomata may appear as the designated entry points for foliar applied substances because the sprayed solution should simply infiltrate the leaves through the stomatal pores. However, both practical experience and theoretical considerations make clear that this is not the case. If stomata could be infiltrated spontaneously by solutions on the leaf surface, this would happen during every precipitation event, at least when stomata are present on the upper leaf surface. Leaves infiltrated by water can be easily identified with the naked eye because of the darker color of the infiltrated tissue. Moreover, if water could easily infiltrate the leaf interior and occupy all the normally air-filled intercellular spaces, diffusion of CO_2 to the sites of photosynthesis in the mesophyll cells would be strongly restricted. After rainfall, the rates of photosynthesis would decrease dramatically until the infiltrated water had transpired, which would take at least several hours. Apparently, stomata are protected against the infiltration of aqueous solutions due to their specific architecture (Schönherr and Bukovac, 1972).

Although both common sense and scientific considerations exclude the possibility of spontaneous infiltration of stomata by water and solutions, many scientific studies have shown clear evidence of a promoting effect of stomata on foliar uptake. In many studies rates of foliar uptake into hypostomatous leaves, i.e., leaves with stomata only on the lower leaf sides, were higher through the lower (abaxial) leaf sides than through the upper (adaxial) side. Other studies reported positive correlations between rates of uptake and stomatal density or stomatal aperture.

The reason for this apparent contradiction is that stomatal uptake of foliar applied fertilizers was assumed to be possible only when the complete solution, i.e., the dissolved solute (= the fertilizer salt) plus the solvent (= water) entered the leaf. This uptake process is also known as 'mass-flow'. Infiltration of stomata by mass-flow can be induced when the surface tension of solutions is lowered by the addition of effective surfactants, such as certain organosilicones.

Meanwhile, it is clear that the assumption of infiltration of stomata by mass-flow as a prerequisite of stomatal uptake of normal solutions was wrong. It has been shown that uptake of solutes such as fertilizers occurs by diffusion, not by mass-flow. The final evidence for this mechanism was the observation that hydrophilic particles (43 nm diameter) suspended in water entered leaves through stomata by diffusion along the walls of the pore (Eichert et al., 2008). However, it was also shown that only a small portion, usually less than 10% of stomata covered by a foliar-applied droplet of solution, are penetrated (Eichert and Goldbach, 2008). It is therefore likely that the penetrability of stomata is not a native, *a priori* property of stomata but that it is acquired *a posteriori*. This possibly occurs by modifications of the, initially rather hydrophobic, pore wall cuticle, due to the effect of, for example, deposited hygroscopic particles, microbes growing in the stomata chamber or salts ascending the pore, rendering it more wettable (Eichert and Burkhardt, 2001). Although not all stomata present on the leaf surface are involved in foliar solute uptake, the contribution of this penetration pathway may be very important and, depending on the type of solute, be as great or even greater than the cuticular route (Eichert and Goldbach, 2008).

Role of external factors

Humidity effects

Humidity effects on solute concentration on the leaf surface

Foliar-applied solutions are usually rather diluted and thus not in equilibrium with the water potential of the atmosphere. They will therefore start to evaporate as drops on the leaves or even before they reach the leaf surfaces. This will result in a reduction of droplet volume accompanied by an increase in solute concentration. During equilibration with the atmosphere, solutions may dry out completely or remain liquid. The final state mainly depends on external air relative humidity (RH) and the type of solute.

When humidity increases, previously dried residues can absorb water from the atmosphere and re-dissolve in this water. For each pure solute, there is a certain threshold RH above which this process starts. This threshold is called deliquescence relative humidity (DRH) or the deliquescence point. The value of DRH is specific for a given solute and is affected by temperature.

If the RH is below the DRH, solutions can completely dry out during equilibration with the atmosphere. This process is called efflorescence. Efflorescence often occurs at values of RH well below the DRH (Fernández et al., 2020). In contrast to DRH, the efflorescence humidity (ERH) depends on the actual conditions and therefore no defined ERH values exist. Efflorescence of solutions below DRH is the result of kinetic inhibition. This can occur in the absence of crystallization nuclei, which normally trigger the crystallization process. These nuclei can for instance be, other salt crystals, small dust particles or specific surface structures.

Both DRH and ERH are important parameters controlling foliar uptake processes: ERH controls the initial drying of fertilizer spray drops while DRH affects the re-hydration of droplet deposits due to e.g., dew, fog or high environmental RH (Fernández et al., 2020). If RH is at, or just above, the DRH or ERH, solute concentrations are maximal. With increasing RH above the DRH, concentrations decrease and theoretically approach zero when RH increases to saturation.

The concentration gradient between the solution on the leaf surface and the leaf interior is the driving force of foliar uptake, therefore, RH will have a strong effect on foliar penetration rates. Moreover, at RH below ERH uptake will cease due to immobilization on the leaf surface. Uptake will resume, however, once RH increases again above DRH, e.g., during the night. The weather conditions and the diurnal rhythm of RH and temperature will thus result in fluctuating concentrations on the leaf surface, making the prediction of rates of uptake difficult under field conditions. Values of DRH and ERH differ considerably between fertilizer salts of the same element (Table 2). The appropriate choice of fertilizer salt may thus help to avoid excessive uptake rates and thus leaf burn.

Table 2 Nutrient carriers normally used in foliar spray formulations.

For selected compounds values of deliquescence relative humidity (DRH) are given.

Based on data from Fernández V, Sotiropoulos T and Brown P (2013) *Foliar Fertilization: Scientific Principles and Field Practices*. First edn. IFA: Paris, France.

Humidity effects on the permeability of leaf surfaces

Increasing RH leads to cuticular water sorption as explained above, and thus facilitates the permeability for polar solutes. It has been shown that an increase of RH from 50% to saturation may increase the permeability of isolated cuticles for ions by two orders of magnitude (Fernández and Eichert, 2009). Stomatal aperture may also react to air humidity. In dry air, plants may close stomata to avoid excessive water loss. Control and adjustment of stomatal aperture, however, is a complex process governed by a range of additional interacting factors, such as soil water availability, plant water status or irradiation. Therefore, no strict relationship between RH and aperture exists and the stomatal penetration pathway will thus probably be less RH dependent than the cuticular pathway.

Overall humidity effects on uptake rates

The RH affects both the solute concentration of fertilizer spray drops deposited onto leaf surfaces and permeability of the leaf surface, at least of the cuticle. Below ERH (drying of drops) or DRH (re-wetting of dry residues) foliar fertilizers are dry and practically no uptake can be expected. Immediately above ERH or DRH solutions are at saturation, solute concentrations are maximal and so is the driving force of uptake. When RH increases to saturation, solute concentrations will decrease due to dilution by the water absorbed from the atmosphere. However, with increasing RH leaf permeability will increase. Therefore, RH has a counter effect on the driving force of uptake and the permeability of the leaf. The resulting rates of uptake can be predicted, in a similar way to Ohm's law, from the product of both parameters, driving force and permeability, according to:

$$F = \Delta c \times P, \quad (2)$$

where F is flux (mol m² s⁻¹), a measure of rates of uptake, Δc (mol m⁻³) is the concentration difference across the leaf surface responsible for the driving force, and P is the permeance (m s⁻¹, see Eq. (1)).

This simple equation supports the conclusion that with high RH (close to or at saturation), when leaf permeability is very high, rates of uptake will nevertheless be low because of the small solute concentrations on the leaf. Therefore, the widespread assumption that high RH will result in the highest rates of foliar uptake is not necessarily true. Rather moderately high RH, at best just above DRH or ERH of the fertilizer salt may result in the largest uptake rates.

Environmental effects on the barrier properties of leaf surfaces

The prevailing environmental conditions during plant growth have a direct influence on the structural and chemical composition of the leaf surface. They may for example, affect cuticle thickness or amount and composition of epicuticular waxes. This will influence wettability and permeability, and thus rates of uptake from foliar sprays. Shading during plant development may decrease the amount of wax per leaf area, whereas high temperatures can modify the morphology and composition of epicuticular waxes. Relative humidity affects the amount of wax per leaf area and wax crystal morphology.

In general, young, partially expanded leaves and fruits are regarded as more penetrable than mature plant parts. This may be linked to, for example, the presence of trichomes, increased stomatal densities and stomatal functionality. However, the barrier function of the surfaces of older plant surfaces can be modified by the erosion of waxes, mechanical injuries and pathogens.

Nutrient deficiencies may also affect leaf structure and function, also including the leaf surface. Nutrient deficiencies may cause changes in trichome or stomatal density and morphology. For example, compared to Fe-sufficient peach and pear leaves, Fe-chlorotic leaves were found to have decreased stomatal pore size and conductance, in addition to lower leaf cuticle weight per unit surface and concentration of soluble cuticular lipids (Fernández et al., 2008). Effects on leaf surface properties and permeability were also reported in relation to deficiencies of other nutrients such as K, Mn, B, phosphorus (P) and Zn. In most cases, nutrient deficiencies decreased the permeability of leaf surfaces and thus rates of uptake. Hence, existing nutrient deficiencies may hamper their correction by foliar sprays. This supports one of the basic principles of plant nutrition: it is better to prevent than to cure nutrient deficiencies!

Effects of adjuvants

Adjuvants (literal translation: 'helpers') are chemicals added to foliar-applied solutions to facilitate the penetration process. They may have different modes of action: 'surfactants' reduce the surface tension of the spray solution with the aim of increasing the contact area between liquid drops and leaf surface. 'Stickers' aim at avoiding the run-off and drip-off of sprays. 'Humectants' are added to keep the active ingredients moist and thus available for uptake. 'Plasticizers' increase the plasticity of the cuticle, thereby enhancing the penetration rates of solutes.

Selection of an appropriate adjuvant is often crucial for improving penetration rates, and this will depend on a range of factors such as properties of the target surface, the compound to be applied and its concentration. However, surfactants may also have an effect on leaf physiology for example by increasing leaf transpiration or altering the structural or chemical composition of the cuticle.

Practical importance of foliar application of nutrients

Foliar fertilization is of increasing importance in agricultural production worldwide. The application of foliar sprays, either as a supplement for root applications or under conditions of limited nutrient availability in the soil, can help to preserve crop yield and quality with low environmental impact. While foliar fertilization has been traditionally used to correct nutrient deficiencies, there is an increasing trend to using nutrient sprays to prevent deficiency symptoms, particularly for elements with limited phloem mobility such as Ca or micronutrients. In commercial agricultural production, foliar fertilization is of particular practical relevance under the following conditions:

Poor nutrient availability in soils

Many soil properties can limit element solubility and the uptake of nutrients by plant roots. For example, due to the poor availability of P in many soils, P is a widespread limiting factor for crop production worldwide. On the other hand, the limited solubility of several micronutrients such as Fe, Mn, Cu and Zn is also a common problem in calcareous soils with high pH, which is exacerbated by drought. The application of micronutrient sprays to control or avoid the occurrence of micronutrient deficiencies under conditions of limited nutrient availability in the soil is one of the most important practical uses of foliar fertilization worldwide.

Foliar Fe sprays may induce the re-greening of chlorotic leaves, and restore some leaf physiological properties such as the rate of photosynthesis or transpiration. Manganese and Zn foliar sprays can also be very effective for overcoming Mn and Zn deficiency in crop plants.

However, micronutrient sprays may have a low efficacy in terms of limited distribution to different plant parts and metabolic functionality.

Dry topsoil

In semi-arid regions, the lack of available water in the topsoil often reduces nutrient availability during the growing season, even though water may still be available in the subsoil. Under conditions of water and nutrient shortage, crop yield and quality can be ensured by complementing standard root fertilization with foliar sprays. Foliar sprays may also contribute to plant drought

tolerance, but physiological effects caused by drought (e.g., stomatal closure) may decrease the rate of foliar absorption of foliar fertilizers.

Periods of large nutrient demand

During the reproductive stage, root nutrient uptake may be compromised by the transport of carbohydrates to reproductive organs (sink competition). Foliar fertilizer application during such periods can compensate for reduced root nutrient uptake during these periods. Foliar nitrogen (N) sprays have been found to be beneficial for legumes when there is sink competition for carbohydrates between developing seeds and root. In cereals, grain quality and yield can be increased by late-season foliar N applications.

Boron plays a key role in plant reproduction, thus it is important to ensure an adequate plant B status, and foliar sprays can be useful for this purpose. In annual crops, B sprays before flowering have proven effective. In fruit-tree species with high B phloem mobility, foliar B sprays supplied in autumn can successfully increase the B concentration of reproductive and vegetative organs, and improve fruit setting in the next growing season.

Foliar sprays of nutrients such as N, K, B and micronutrients are often supplied to fruit crops during the growing season to improve flowering, fruit set and plant development, for example.

Improving quality of horticultural commodities

The occurrence of Ca-related disorders in fruits and vegetables is a major problem affecting the marketability, storability and shelf-life of horticultural commodities. Such damage develops during fruit growth and is caused by localized Ca deficiency in plant organs with generally low transpiration. Calcium has poor phloem mobility and its supply to the fruits depends on Ca delivery via xylem flow. Because of the low transpiration rate of fruits which have low stomatal densities or non-functional stomata, little Ca will reach these organs even under good Ca availability conditions for root absorption. Subsequently, Ca sprays applied to the aerial part of fruit trees are often supplied during the growing season to prevent the occurrence of Ca-related disorders and improve fruit quality and storability.

Bio-fortification

Bio-fortification is the enhancement of the nutritional value of food crops for human consumption. Foliar sprays applied alone or in combination with root fertilization can increase the concentration of micronutrients in foods and alleviate micronutrient deficiencies in humans, as reported after micronutrient enrichment of grain crops or rice (*Oryza sativa* L.). The bio-fortification of staple food crops or horticultural commodities with foliar sprays of beneficial elements such as selenium (Se) or iodine (I) can also be achieved.

Bio-fortification has been intensively studied in the case of Zn. Almost 50% of soils in cereal growing areas in the world have been found to be deficient in Zn, either because Zn concentrations are inherently low or Zn availability is reduced by high soil pH. In many cases, foliar Zn application has been found to be superior in increasing grain Zn concentration in cereals compared to soil application (Cakmak and Kutman, 2018).

Efficiency of foliar nutrition

Theoretically, foliar fertilization is more target-oriented and environmentally-friendly than soil treatments because nutrients are delivered directly to sink plant organs and there is less risk of environmental contamination. Plants often have a rapid response to nutrients supplied as foliar sprays compared to root fertilization. However, the efficiency of foliar sprays can be variable because of the complexity surrounding the foliar uptake process. Consequently, complete reliance on foliar sprays for meeting plant nutrient demand in full cannot be achieved in commercial agriculture, because this may compromise crop yield and quality, particularly in the case of macronutrients which are taken up in large amounts by plants.

The efficacy of foliar nutrient sprays is determined by many environmental, physico-chemical and physiological factors associated with the plant, the environment and the spray formulation. An array of problems limiting the effectiveness of foliar sprays may arise, such as:

1. Limited leaf wetting and retention of sprays when treating unwettable, even water-repellent leaves, or if applying spray solutions without appropriate surfactants to unwettable plant surfaces.
2. Washing off by rain following the application of nutrient sprays.
3. Low rates of nutrient uptake due to low foliar permeability as affected by, for example, plant physiological factors or environmental conditions.
4. Rapid drying of spray solutions, particularly under low RH and high temperature conditions, resulting in poor nutrient uptake.
5. Low mobility of the nutrients sprayed within the plant following foliar application
6. Limitations related to the concentration range of foliar-applied macronutrients for meeting plant demand without inducing phytotoxicity (leaf burn).

7. Foliar fertilization may support spore germination and colony growth of pathogens
8. Potential transient nutrient imbalances when single nutrient sprays are supplied to the plants.

Leaf burn and defoliation are major risks when applying foliar sprays. Different degrees of damage may occur, ranging from the appearance of necrotic spots to complete defoliation. This can be the result of excessive nutrient concentrations, the use of hygroscopic active ingredients or the presence of surfactants, which significantly increase the rate of penetration of the applied nutrients and are often phytotoxic when applied at large concentrations. Environmental conditions during application are also important. Leaf burn is more likely to occur when solutions are sprayed during periods of high irradiation and high temperature. Therefore, application in the morning or evening is usually recommended.

Summary

Although leaves are not designed to be natural sites of nutrient uptake, fertilizers can be taken up through the leaf surfaces. Foliar applied substances penetrate the external surface either through the cuticle or through stomata. In contrast to root uptake, foliar uptake is a passive process solely ruled by the laws of diffusion. Therefore, care has to be taken to avoid the negative effects of foliar application such as leaf burn.

In most cases leaf damage results from excessive uptake. This risk can be reduced by using adequate nutrient concentrations and selecting appropriate compounds. Salts differ in their ability to absorb and bind water from the atmosphere. This has a strong effect on the feasibility of nutrient absorption by the leaf surface because uptake requires that the substances are present in dissolved form. Efflorescence, the drying of foliar sprays, occurs at different levels of relative air humidity (RH). The level of RH at which solutions dry out is named efflorescence relative humidity (ERH). Likewise, deliquescence, the re-wetting of salt residues, occurs after RH has exceeded a defined threshold; the deliquescence relative humidity (DRH). Values of DRH and ERH differ considerably between salts, and the appropriate choice of fertilizer salt may help to avoid excessive rates of uptake and thus leaf burn.

Foliar nutrient application is of great importance whenever nutrient availability in the soil is the limiting factor. This is a typical problem in alkaline soils where micronutrients such as Fe or Mn are immobilized. Application of calcium sprays in fruit production is another important field of application.

Foliar nutrient application is a target-oriented and environmentally-friendly fertilization strategy that reduces the risk of environmental contamination. It allows faster nutrient delivery to plants compared to root fertilization. In the case of micronutrients, but also for calcium supply to fruits, foliar fertilization is already an established fertilization strategy with increasing practical importance.

Abstract

Mulches, both organic and inorganic favorably ameliorate the hydrological regime of soil, and are gaining significance in the context of climate change. In-situ mulching practiced under conservation agricultural systems can replace crop residue burning. Similar to mulches, growing cover crops can protect soils from erosion and enhance soil fertility. However, mulching has some limitations such as the disposal of non-biodegradable plastic mulch, competing demand for crop residues by other enterprises, lack of machinery and knowhow among the farmers for field operations, particularly in the case of developing countries. Appropriate policy decisions may be taken for addressing these limitations.

Introduction

Mulch is a layer of dissimilar material separating the soil surface from the atmosphere, and its application aims to modify the soil environment beneficially (Acharya et al., 2005, 2018). Mulch may be organic (crop residues, stubble mulch etc.) or inorganic (plastic sheets, gravels etc.). It may be generated in-situ by crop residues left on the soil surface or it may be living such as a perennial legume mulch, or it may be grown or produced ex-situ for example, straw, sawdust, plastic products etc. The practice of mulching has been widely used as a management tool for centuries in many ancient civilizations. The Great Plains region of USA, which was once a dust bowl, has become a major grain producer with the adoption of conservation tillage whereby crop residues or flattened straw mulch are left on the surface. The idea of using plastics as a mulch originated in Hawaii, where it was successfully used in pineapple cultivation.

Cover crops provide ground cover, and thus growing cover crops is a principal agronomic approach to erosion control and enhancing soil fertility. The merits of cover crops are well established. There is, for example, a wide choice of species and planting techniques that allow adequate plant establishment in most temperate or tropical settings, thus making cover cropping feasible under most soil, climatic, and cultural conditions. The goals of cover cropping have varied historically between single- and multi-purpose, and may range from single crop stands grown principally for ground protection, to mixed stands of food or feed species. The latter are, in large part, established to produce a crop (e.g., grain or hay in north-temperate climates and pulses in tropical climates), but eventually all systems result in soil quality improvement that may take the form of: (1) physical conditioning; (2) nitrogen accumulation; and (3) organic matter enhancements to the benefit of any arable terrain, be it sloping or flat land.

For example, the Ministry of New and Renewable Energy (MNRE, 2009), Government of India has estimated that about 500 Mt. of crop residues are generated every year and of these 91–141 Mt. of residues are burnt. The rice (*Oryza sativa* L)–wheat (*Triticum*

aestivum L.) cropping systems in the north western (NW) states of India produce about 34 million tonnes of rice residues of which Punjab alone contributes about 65%. The mechanized harvesting and threshing of rice using combine harvesters is a common practice in NW India. In the process, residues are left behind the harvesters in a narrow strip (windrow) in the field. Disposal or utilization of the leftover residue in the short window of 10–20 days for the timely planting of a wheat crop is a difficult task. Therefore, the farmers commonly opt to burn the rice residues because of lack of access to user-friendly, cost- and time-effective options. It is estimated that in the NW states of India about 23 million tonnes of rice residues are burned annually (NAAS, 2017). This adversely affects air quality in adjacent areas resulting in various health hazards in addition to degrading soil health. It is estimated that burning 1 tonne of rice residue releases 13 kg particulate matter, 60 kg CO (carbon monoxide), 1460 kg CO₂ (carbon dioxide), 3.5 kg NO_x (nitrogen oxides), 0.2 kg SO₂ (sulfur dioxide). The black carbon emitted during residue burning warms the lower atmosphere and it is the second most important contributor to global warming after CO₂. The emission of high levels of PM_{2.5} and PM₁₀ in the air causes chronic diseases like cardiopulmonary disorders, irrecoverable lung capacity or asthma in human populations. If part of this residue was utilized as mulch, it would contribute to improving the soil, environment and human health.

This chapter reviews the types of mulches and cover crops and methods of their application to soil and limitations to the adoption of mulches and cover crops by the farming community. A companion chapter deals with the role of mulches and cover crops on soil health and climate resilient agriculture.

Types of mulches

Soil itself forms a mulch called “dust or soil mulch” owing to the formation of a dry layer at the soil surface, the effectiveness of which depends on its texture (Prihar et al., 1968), thickness and porosity (Acharya and Prihar, 1969), nature of cations in the exchange complex and prevailing climatic conditions (Acharya and Abrol, 1978; Acharya et al., 1979). Apart from soil mulch there are different types of materials ranging from natural plant residues, to gravel to various industrial products such as paper or plastic sheets, which are used as mulches.

Organic mulches

Organic mulches include live mulch, cover crops, in situ mulching under conservation agriculture and ex situ mulches using the materials derived from natural sources, such as field crops, trees, or natural bio-waste products.

Organic residue mulch

These include hay, straw, wood chips, bark, sawdust, wood shavings, peat moss, compost, wastes from cattle sheds, farmyard manure (FYM), grass clippings, paper, and materials such as cocoa shells (*Erythroxylum coca* Lam.) and buckwheat (*Fagopyrum esculentum* Moench) hulls. Organic materials for mulching should be stable and remain in place at least through the growing season of an annual crop and longer for perennial crops. More durable organic materials having high C:N ratios (>80:1) and provide longer-lasting benefits compared with readily decomposable plant residues. Durability of organic mulches depends upon its composition. Factors influencing the rapidity of residue decomposition include the C:N ratio, cellulose and lignin contents, climatic conditions, and community composition of soil microorganisms. High lignin and cellulose containing cereal straws produce more weather-resistant mulches than legumes (Fig. 1).

The effectiveness of organic or vegetative mulches also depends upon their thickness. For adequate protection of the soil the mulch should not be too thick suppressing plant growth. Vegetative mulches, with their low thermal conductivities, decrease the conduction of heat into and out of the soil. Therefore, the mulched soil is cooler during the day and warmer at night than bare soil; it

Fig. 1 Straw mulching in a vegetable crop. Source: <https://horticulture.ucdavis.edu/>.

insulates the soil surface. Vegetative mulches also affect soil temperature by changing the radiant energy balance of the system. The radiation balance is influenced by the reflection of incoming radiation by surface residues, differential heating of soil and air, and reduction in evaporation of soil water from the surface. Soil temperature generally decreases as reflectance increases. Age of the residue, color, geometry (standing, flattened or matted), distribution and amount are the main characteristics that affect radiation reflection. Reflection is usually greatest from bright residues such as wheat straw and decreases with residue aging (discoloration) and decomposition.

Organic mulches have the advantage of being biodegradable and will eventually be broken down by microorganisms, increasing soil organic matter (SOM) content and improving soil structure or tilth. Organic mulches reduce the rate of evaporation from the soil surface, depending on their thickness, type, orientation and color. The material density of mulch affects the thickness and surface coverage obtained for a given weight, therefore, a low density material such as wheat straw reduces evaporation more effectively than higher density materials such as sorghum (*Sorghum bicolor* (L.) Moench) stubble or cotton (*Gossypium hirsutum* L.) stalks.

Crop residue mulch may be of two types, i.e., surface mulching with crop residues or rooted crop residues. One of the principles of conservation agriculture is that at least 30% of the area should be covered with crop residue mulch. After crop harvest with a combine harvester, the field is left with crop residues with their roots anchored to soil, which serve as mulch and the next crop is sown into this mulched condition using "Happy seeder or Turbo seeder" techniques.

Wastes from cattle sheds as mulch

Many indigenous technical knowledge (ITK) has been developed by the farmers in countries of the developing world to prepare nutrient rich mulch material, which can be followed under similar agroclimatic regions elsewhere. For example, in sub-mountainous hill regions of north-west India, farmers spread wastes from cattle-sheds in standing maize (*Zea mays* L.). Leafy materials like Basooti (*Adhatoda vasica*), Bhang (*Canavisa sativa*) and other locally available wild shrubs with prolific growth rates during the monsoon season and have no fodder value, therefore, are spread beneath animals to provide bedding. This material is collected each day together with dung and urine and spread in the standing maize crop. This makes a good mulching material to conserve and carry over the moisture from the time when the monsoon starts receding (Acharya et al., 2001). The material is left over after the maize harvest and is incorporated into the soil at the time of field preparation for sowing wheat. The practice not only conserves moisture but also enriches the soil to provide nutrients to the subsequent wheat crop because some of the materials are nutrient rich, for example, Basooti leave residues that contain on average 3.4% N, 0.4% P and 3.8% K.

Spreading of farm yard manure (FYM) as mulch

Farmyard manure has an important role worldwide in supplying humus forming materials which improves soil structure, water holding capacity, microbial populations and their activity, cation exchange capacity and resistance to soil erosion. For example, in the mid-hill region of north-west Indian Himalayan region, instead of incorporation FYM is spread over the fields after the sowing of wheat. This is done primarily to moderate the thermal regime as the minimum soil temperature during winter is very low. Depending upon the quantity applied, the coverage provided by FYM also helps in moisture conservation of seed-zone depth in addition to enriching soil fertility (Acharya et al., 2001). This technology can be adopted in similar agroclimatic regions for improving soil health and crop productivity in other regions of the world.

In the cold desert Himalayan regions the winter temperature goes as low as -30°C making life difficult for both humans and livestock. Here, cattle sheds are attached to the farmers' houses. In general, the ground floor in each house is used as a cowshed so that animals can be conveniently looked after during winter. The green leaves of pine trees (*Pinus sylvestris* L.), dry pine leaves, dry grasses or other bushes are put into the cattle shed as bedding. The dung and urine are collected from these beds every 3–4 days and stored in a heap within the cattle shed during winter months, so that decomposition is enhanced by the relatively high temperature conditions indoors. It is then placed in small heaps in the fields. These heaps are covered with a thin layer of soil to avoid dispersion of the manure by wind. This material is converted in due course to farmyard manure (FYM). This technology can be adopted in similar agroclimatic regions of the developing world countries.

As the winter season sets in, and before snowfall, the fields are prepared and crops such as coarse grains, wheat, barley (*Hordeum vulgare* L.) and some more remunerative vegetable crops like green pea (*Pisum arvense* L.) are sown. These fields are then covered with a layer of FYM as mulch. During summer, as temperature rises and the snow starts to melt, the FYM provides not only good nutrition but also a good cover to moderate the hydrologic and thermal regime for better seed germination. Beneath the mulch, chemical and biological activity are enhanced that encourage further decomposition and release of nutrients. The early crop of green pea with higher productivity fetches a good price in the market not only for its taste but also for its other quality attributes.

Cover crops

Live or cover crop mulch is also an important organic mulch; it is a covering of living plant material that is planted or allowed to remain after another crop has been planted. The live mulch system is based on the principles of mixed cropping. For example, a perennial legume might be established to smother weeds and then a seasonal grain crop is grown in strips through the cover crop. Cover crops succeed if they are low-growing and do not compete for light, moisture or nutrients with the main crop. The live mulch system is more successful in humid and sub-humid regions with little or no water deficit than in semiarid or arid regions. It has similar benefits to surface-applied organic mulches such as increased soil carbon content, increased rainwater infiltration and reduced soil erosion. Cover cropping is seen as green culture; given its role in SOM accumulation, soil structure improvement, soil

fertility increase, and weed and disease suppression with minimal or no chemical inputs. Thus, it should gain in popularity and political importance with sustainable agricultural practices now considered vital worldwide for soil and human health.

Types of cover crops

The three basic principles of conservation agriculture are (i) reduced tillage, (ii) residue retention (at least 30% of the soil surface should be covered) and (iii) crop diversification (FAO, 2019). The purpose of crop diversification is to select crops that will cover the soil year round; legumes are mostly preferred for this purpose. In general, the choice of cover crops depends on many factors viz., crop, soil, climate conditions, availability of resources and socio-economic factors. Within the limits of adaptability of any cover crop to prevailing climate and soil conditions, foremost among the desired characteristics is establishment vigor, persistence to the end of the required period, and ease of eradication to make way for the succeeding crop, usually the main crop (Edwards and Burney, 2005). The termination of cover crops may be achieved by their incorporation into the soil by tillage or by the application of broad spectrum herbicides, which is called brown manuring. The age-old practice of green manuring or the later developed practice of brown manuring are examples of cover crops.

Suitable cover crops include both monocotyledonous and dicotyledonous species. The former botanical group, which comprises mostly cereals and grasses, are doubly useful in soil erosion control because, in addition to the direct role of their vegetation shielding the soil surface against aggregate breakdown by raindrop impact, their fibrous root systems bind the soil, thus increasing its resistance to entrainment by overland flow. On the other hand, the soil-protection attributes of a dicotyledonous cover are due to their broad-leaf nature, specifically their characteristically overlapping system of leaves geared to intercepting rainfall and minimizing splash (Fig. 2).

Success in cover-crop establishment and function depends on species choice. But species suitability is hardly ever limiting considering the wide range of potential cover crops.

Cover crop mulches suppress weed growth through modification of the microclimate and release of allelochemicals. However, yield suppression of the food crops has been reported due to allelopathic effects of the cover crop on the main crop and competition for moisture during periods of drought stress. Cover crops also help to increase biodiversity in the system and help in disease and pest control. Some crops like the cereal rye (*Secale cereale* L.) and hairy vetch (*Vicia villosa* Roth) can be used safely as cover crop mulches. Cereal rye is one of the best winter-hardy cover crops grown in the mid-western U.S. Perennial ryegrass (*Lolium perenne* L.) is a potential cover crop that is commonly used as a living mulch for some vegetables such as cabbage (*Brassica oleracea* L.).

Living mulch, on the other hand, is a type of low-growing ground cover crop that blankets soil throughout the growing season of the main crop. It can be incorporated with the main crop by inter-seeding or over-seeding, co-seeding or otherwise companion planting. Some of the potential living mulches are: hairy or crown vetch, flatpea (*Lathyrus sylvestris* L.), clover (*Trifolium* L.), ryegrass etc. Living mulches grow for a long time with the main crop, whereas cover crops are incorporated into the soil or killed with herbicides.

Other organic mulches

Recycled paper is an important organic mulch, and can be considered as a biodegradable alternative to plastic mulch. Paper does not require disposal at the end of the season and its use can reduce solid waste and energy costs. Paper might decompose too rapidly, however, to provide ground coverage throughout a growing season. Treating the paper with waste cooking oil delays its breakdown and enhances soil warming by increasing the paper's translucency to sunlight.

Fig. 2 *Crotalaria* cover crop (<https://www.istockphoto.com/photo/crotalaria-cover-crop-keeps-soil-moisture-gm487086108-72723713>).

Inorganic mulches

Various inorganic materials such as plastic film, gravels, crushed rocks etc. are used as mulches. These do not add nutrients or humus to soil and do not decompose, except after long exposure to weathering.

Plastic mulch

Plastics are the most widely used inorganic mulch materials. Plastic film has played a major role in plant cultivation by creating some mechanical protection at the soil surface and a suitable microclimate in terms of temperature distribution, retention of humidity and the supply of carbon dioxide to the stomata of lower leaves of small plants. Plastic mulches have been used commercially for vegetable production since the early 1960s. It can be used very effectively with trickle or drip irrigation particularly for the cultivation of vines (*Vitis vinifera* L.) and strawberries (*Fragaria × ananassa* Duchesne) where it encourages lateral development of the root system. In many of the developed countries plastic film, such as low-density polyethylene (LDPE) film, is rapidly replacing conventional vegetative mulching because of its effectiveness and commercial viability, particularly for high value crops. Around 30–60% of the cultivated area is covered with a thick polythene film (30–150 µm). The plants can grow through holes in the LDPE film. It is often used under gravel or stone mulches for ornamental plants. The effectiveness of the plastic mulch depends upon its color, which determines the energy-radiating behavior and affects the temperature of the surface of the mulch and of the underlying soil. Recently, new plastic products for farmers such as photodegradable, co-extruded (black/white), and different colored mulches. They can maintain cool soil temperatures during summer in tropical countries, increase warming of soil in spring in temperate regions and repel aphids with the silver colored mulch. By raising the soil temperature, plant growth is accelerated producing earlier yields in temperate regions. Harvest can be 7–14 days earlier under black plastic while clear plastic can accelerate harvest by 21 days. For enhancing the earliness of vegetable crops in temperate regions, the mulch maximizes the soil-warming near infra-red radiation and minimizes the amount of visible light transmitted, which increases weed growth under the mulch.

Plastic mulches are mainly used for high value vegetable and cash crops because of the high cost and difficulty of keeping it in place (Fig. 3). Disposal of the plastic is an environmental concern (Steinmetz et al., 2016), and it is always completely removed from the field and can remain in soil for a long duration (Briassoulis et al., 2015). Liu et al. (2014) reported that long-term use of plastic film mulches in Chi/na has resulted in an estimated accumulation of 50–260 kg hm⁻² of residual plastics at 0–20 cm soil depth, which inhibited the growth of subsequent crops. Also other environmental problems are, for example, carbon footprint of plastic mulches (life cycle assessment), microplastics in soils being taken up by crops and animals, and ending up in the food chain, and potentially faster removal of pesticides from the plastic cover. There is also debate around potential degradation of soil quality under plastic mulches through shifting C/N ratio, reduction of carbon stocks, shifting microbial community composition to more fungi-dominated etc. Biodegradable plastic mulches have now been developed to resolve some of the environmental concerns (Bandopadhyay et al., 2018). Muskmelons (*Cucumis melo* L.), tomatoes (*Solanum lycopersicum* L.), pepper (*Piper nigrum* L.), cucumbers (*Cucumis sativus* L.), squash (*Cucurbita maxima* Duchesne), eggplants (*Solanum melongena* L.), watermelons (*Citrullus lanatus*) and okra (*Abelmoschus esculentus* (L.) Moench) are some of the vegetable crops that have shown a significant increase in early yield, and fruit quality when grown on plastic mulch. Some less valuable crops like sweet corn (*Zea mays* L.), snap beans (*Phaseolus vulgaris* L.), southern peas (*Vigna unguiculata* (L.) Walp.) and pumpkins (*Cucurbita pepo* L.) have also shown similar responses in temperate climates. Based on the ability to transmit, absorb or reflect specific wavelengths, plastic mulches are divided into the following categories:

- a. *Black plastic mulch*: Black is the most commonly used color of polyethylene mulch. This is chosen more often than clear polythene as a mulch because of its ability to control weeds by excluding photosynthetically active radiation. Black polythene placed in direct contact with the soil can warm the soil to a depth of about 8–10 cm. Under black plastic film the temperature of

Fig. 3 Plastic mulching in a tomato field. Source: <http://www.tomatonews.com/en/>.

- the soil during the day is not significantly higher and in certain cases it is even lower than of bare ground, but during the night the temperature is always 0.5–4 °C higher than that of uncovered ground. This is desirable for warm-season vegetables such as peppers, tomato, eggplants etc. It is also widely used for the cultivation of pineapples in Hawaii, USA for reaping higher yields.
- b. *Transparent or clear plastic mulch*: Clear plastics have the greatest warming potential. They are transparent to incoming radiation and trap the longer wavelengths re-radiating from the soil, thereby producing a greenhouse effect that warms the soil underneath. Under transparent plastic film during daytime soil temperature remains 2–10 °C higher than bare ground while at night differences of 2–4 °C are observed depending upon season, soil type and its moisture content. For warm season crops, such as vines, earlier and higher yields can be achieved with clear plastic mulches. However, as clear mulch is transparent to visible light, weed infestation under it may negate the benefits of soil warming.
 - c. *White plastic mulch*: Under white plastic mulch the temperature always remains lower than the uncovered ground due to its high reflectance and low transmittance of solar radiation. Since energy exchange is very poor, this film is used either in regions with a high level of sunshine where it is required to reduce the energy and lower the soil temperature or in regions of low luminosity where the amount of reflected light can be increased on the lower and middle leaves of crop plants.
 - d. *Colored plastic mulch*: These are opaque, like black plastics, and are made with many different pigments. They do not allow light to pass through, but rather, reflect specific wavelengths of light up into the crop canopy. These mulches may be useful for enhancing crop production. For example, red mulches are effective in promoting growth of tomatoes. The other response observed with different mulch colors is the increase or decrease in insect populations depending on reflected light and possibly temperature. Yellow appears to attract insects, especially cucumber beetle, and silver appears to repel aphids. In addition, pesticide applications could be reduced if instead of spraying it on the entire field, some rows with yellow mulch (e.g., one row of yellow for every five or six rows covered by differently colored mulches) were sprayed with insecticides to control high pest populations. Thus, yellow plastic mulches can be used to attract insects, much like a trap crop (Fig. 4).
 - e. *Infra-Red transmitting mulches (IRT)*: These have been developed recently and are wavelength selective mulches. The effect of IRT mulches on soil temperature is intermediate between clear and black polythene mulches. These mulches are pigmented to reduce the amount of visible light transmitted and, thereby, reduce weed growth underneath. Thus, these blend the soil warming characteristics of clear mulch with the weed control ability of black mulches. The IRTs contain very specific pigments that give them the unique ability to transmit a maximum of near infrared radiation and a minimum (14–16%) of visible light. Some visible light is required to be transmitted to maximize soil warming. The benefits of IRTs are greatest for early season plantings in temperate regions. Though these mulches are more expensive than black or clear plastics, some growers find them useful for high-value, heat-loving crops like melons.

Gravel mulch

Gravel mulching is an age-old practice and can be very effective for water conservation (both in enhancing infiltration and in suppressing evaporation even in layers as thin as 5–10 mm). The problem with this type of mulch is that once applied, gravels cannot be removed, do not decompose and might hinder future farm operations or land uses, and also the high cost of mining, transport and application in the field.

Fig. 4 Colored mulch film. Source: <http://agritech.tnau.ac.in/>.

Crushed rock

Crushed volcanic rock or stones are useful around plants subject to crown rot. Their color influences the temperature of the soil underneath. Black rock absorbs heat and keeps the soil temperature warmer than normal, while white rock reflects sunlight and maintains a cooler temperature below but can generate too much heat for the above ground portion of some plants to survive.

Other materials used as mulch

Sprayable preparations of latex, asphalt, oil, fatty alcohols etc. are also used as mulches for certain high-income crops such as strawberries. They inhibit evaporation by forming monomolecular films on the soil surface. Some water proofing chemicals like silicone application on clods on the soil surface forms a layer of water repellent aggregates. These aggregates then constitute a dry mulch that serves as a barrier to evaporation. This layer also enhances infiltration by allowing the treated surface zone to act as a retention reservoir to prevent runoff.

Methods of mulch application

The methods of mulch application vary with soil type, climate, crop and the type of mulch material used. Paper and plastic mulches are generally spread and fastened down either between the rows or over the rows of the crop. The plant seedlings in the latter case can grow through suitable openings in the material. Plastic mulches used in commercial cultivation are generally applied mechanically. A 15–23 cm border of plastic is usually buried leaving 76–91 cm exposed. Nowadays tractor operated mulch spreaders have been developed for laying plastic mulches in large fields.

Organic mulches are usually spread a few centimeters thick on the soil surface. Their depth depends upon the mulch material and types of crop on which it is applied. Thicker layers are normally placed around trees and shrubs while finer and smaller materials are generally used for small flowers and vegetables. The finer and smaller is the particle size, the thinner the layer needs to be. Thick layers of very fine material block air to the roots of plants. For trees, mulch cover should reach the tree's drip line or the outer perimeter of the branches. It should preferably be kept at least 15 cm from the tree trunk and two centimeters from plant stems.

Under conservation agriculture, sufficient residues remain on the surface after harvest of the previous crop. Sometimes, the left over residues in patches create problems for sowing of the next crop. Some engineering interventions can help in addressing this problem. Recently, a super straw management system (Super-SMS) has been developed by Punjab Agricultural University, Ludhiana (Punjab), India, which comes as an attachment to the Combine Harvester (NAAS, 2017). This straw management system can spread rice residues uniformly during the rice harvest. Then the next crop is sown in the standing crop residue using the Turbo Happy seeder. Harvesting of rice by super-SMS fitted combine harvesters allows concurrent sowing of the subsequent wheat crop, which saves time, energy and requires only one irrigation by utilizing the residual moisture of rice fields. This practice also reduces traffic and compaction. Further, this technology can replace rice residue burning, a problem for air quality.

Mulches are normally applied and spread uniformly on the soil surface except in the case of vertical mulching. Here crop residues, stubble from the previous crop or other agricultural waste materials are placed in vertical trenches at intervals of every few meters to recharge the profile with water and conserve moisture in low rainfall areas of the semi-arid tropics. The few centimeters of stubble above the trenches can also reduce runoff and sediment loss from the field. In vertical mulching, holes are dug around the base of a tree or shrub that is stressed. The holes are filled with a mixture of organic material. The back fill and aeration can dramatically improve root growth and reduce or eliminate stress. The other advantages of vertical mulching include: reduced compaction, increased drainage, oxygen to the root system, soil organic matter, soil organisms, and water retention. The aeration and soil treatment create an environment that mimics nature and allows for greater nutrient uptake, increased root growth and the potential regeneration of a damaged root system.

Limitations of mulching and cover crops

Despite the positive aspects of mulching, it has some limitations, which must be taken into account while following the practice of mulching.

- (i) If mulch is applied before sowing it hinders sowing and many post sowing operations like fertilizer applications, irrigation etc. Mulches pose particular problems for the arable farmer because tillage tools become clogged with the residue, thus planting under the residue is not always successful. Some specific equipment is required for post sowing operations in mulched plots.
- (ii) In shallow potato (*Solanum tuberosum* L.) planting if mulch is managed improperly it may lead to a greater percentage of stolon becoming aerial shoots and more tubers becoming sunburned. The mulch layer in potato fields should be removed once a full canopy is achieved to avoid disease and pest infestation.
- (iii) In areas of high rainfall, thick mulching may lead to waterlogging conditions and provide an environment for disease infestation. If the soil is too wet under mulch, denitrifying bacteria will increase and may cause a loss of N.

- (iv) The effectiveness of mulch depends upon the depth and extent of its coverage. However, if the mulch is applied too thickly it may hinder seedling emergence through the deep impenetrable barrier. Therefore, it is suggested that a thin layer of mulch is used at planting to avoid impeding seedling emergence, then followed with a thicker application once the seedlings are established.
- (v) Plastic mulches usually require pick up and disposal at the end of the season, and their manufacture and disposal entail significant environmental costs because these are not biodegradable, and microplastics especially pose a potential environmental threat. Plastic mulch can interfere with recharge of the soil profile by rain or overhead irrigation, which can lead to water deficits in vegetables if drip irrigation is not used.
- (vi) Numerous phytotoxic substances associated with various crop residues have been shown to limit growth of several crop species reportedly through exudation, leaching or microbial production of allelopathic chemicals.
- (vii) Organic mulches such as grass and straw often contain seeds that allow weeds to grow and hamper crop growth.
- (viii) There are competing demands for crop residues for other uses in the semi-arid tropics of the developing countries. Most of the plant residues are used as cattle fodder, therefore, farmers might not adopt this practice where fodder is scarce. In the tropics, crop residues are also used for fencing, roofing and as a source of household fuel. Mulching is thus practiced under conditions where the marginal return from this practice is higher than its other competing demands.
- (ix) Crop residue mulches reduce the temperature of the surface soil layers. In cool climates, this reduction in soil temperature shortens the growing season of arable crops while in wet areas higher soil moisture may induce gleying and anaerobic conditions. The limiting problem of using residue mulch on the soils in temperate regions is its inability to remove excess water to allow the soil to warm up in time for planting the next crop.
- (x) The mulch competes with the main crop for nitrogen during decomposition if the C:N ratio of the material is high due to immobilization of the soil nitrogen by microorganisms.
- (xi) The surface residue mulch may generate a more favorable habitat for soil and surface-dwelling insects and pathogens. The residue left at the surface reduces water loss, moderates temperature extremes and provides food resources for pests and increases their infestation. Furthermore, for many plant pathogens, residues provide a source of food, a place to live and a place to reproduce. A significant proportion of root infecting organisms, for example, depend upon crop residues for their survival in soil. Root diseases caused by *Pythium* species are favored by wet soils and cool temperature, especially in maize production.
- (xii) In areas of water scarcity, cover crops compete with the main crops for water and nutrients. If the cover crops do not yield any economic output then farmers are reluctant to grow them even though they are beneficial for soil health. Rather than green manure crops, growing short duration legumes may be promoted in between cereal crops, which can serve the dual purpose as cover crop and also yield some economic benefit to the farmers.
- (xiii) Some of the limitations of living mulch include: (a) It competes for nutrients and water with the main crop which can reduce the yield; (b) It slows down the maturity of the main crop; (c) Some mulch produces allelopathic effects on the crop; (d) Specialized management practices are required; (e) The temperature below the mulch is lowered.

Conclusions

Mulching can be considered as a win-win technology because it can solve the problem of straw burning, improve the environmental quality and crop productivity. Mulches can be of organic and inorganic nature. Site-specific mulching practices should be developed. Because mulching improves the soil hydrological regime, this practice can mitigate the adverse effect of climate change and climate variability. Therefore, mulching can be considered as a potential climate resilient technology. However, this technology has some limitations such as the disposal of non-biodegradable plastic mulch, competing demand of crop residues by other enterprises, lack of machinery and knowhow among the farmers for field operations in the presence of mulches, particularly in the case of developing countries. Appropriate policy decisions may be taken to address these limitations. Together with mulching, short duration pulses may be promoted as cover crops in cereal based rotations to improve soil health, reduce soil erosion, and improve crop productivity and farmers' income. Our motto should be "Grains for human consumption and residues for improving soil health."

Abstract

Mulches may improve soil health, moderate the soil moisture regime, buffer temperature fluctuations, facilitate aeration, and crop growth, seedling emergence, root growth, and foster efficient water and nutrient use. Mulching also improves the environment by facilitating carbon sequestration and reducing greenhouse gas emissions from the soil. Similar to mulches, growing cover crops protects the soil, improves biodiversity and is one agronomic approach to erosion control and enhancing soil fertility. Policy decisions to overcome limitations in adopting conservation agriculture, mulching and cover cropping are required to provide technical and financial support to farmers.

Introduction

Mulching has a great potential for improving soil health by favorable modification of the soil hydrological regime, carbon sequestration, minimizing soil erosion, improving agricultural productivity and mitigation of climate change. Developing adaptation and mitigation strategies for the adverse impacts of climate change are amongst the most serious challenges of the present century. With increasing awareness of the effects of climate change by both national and international bodies, ensuring climate resilience has become a major goal. The aim of such efforts is to address the vulnerability that communities, states, and countries have to the environmental consequences of climate change. Currently, efforts for climate resilience encompass social, economic, technological, and political strategies that are being implemented at all scales of society. Various climate resilient technologies have been developed in agriculture to mitigate the impact of climate change. For example, the National Initiative for Climate Resilient Agriculture by the Government of India has outlined some technologies in this context: resource conservation practices and technologies for natural resource management, and efficient use of resources and inputs for improved crop, livestock and fisheries production etc. In situ retention of biomass and crop residues as mulches has been identified as a climate resilient technology for improving soil health, soil moisture conservation and enhancing water-use efficiency. Mulch has a buffering effect and it dampens the influence of environmental factors on soil. The magnitude of this effect depends upon the quality, quantity and durability of the mulch material, soil type and climatic conditions. Mulching influences the soil hydrological and thermal regime through the radiation balance, rate of heat and water vapor transfer, and heat capacity of soil. Thus it can protect the crop from the adverse impact of climate change and climate variability. Organic mulches add nutrients to soil through microbial decomposition and contribute to carbon sequestration, which can be used as a mitigation strategy for global warming.

Mulching also improves the physical soil conditions by enhancing soil aggregation, which helps in carbon sequestration and conservation of water in soil by reducing evaporation, increasing infiltration and retarding runoff and erosion, favorably modifies

the soil's thermal regime, improves the soil chemical environment and biological activity in soil. Modification of the soil microclimate by mulching favors seedling emergence, root proliferation, and suppresses weeds. Thus the soil edaphic environment under mulches improves crop productivity, enhances input-use efficiency and reduces environmental pollution. It is useful as an alternative to cover crops in dry areas where insufficient rain prevents their establishment before the onset of heavy rain or strong winds, or where a cover crop competes for moisture with the main crop. However, in areas with assured water supply cover crops serve as a useful technology to improve soil health and carbon sequestration. Improper application of mulches, i.e., too thick a layer of mulch can lead to an anaerobic environment under heavy rainfall leading to loss of nitrogen through denitrification, disease and pest infestation, some allelopathic materials produced in some crop residues retard crop growth, and mulches with high C:N ratios can lead to immobilization of N. A proper site-specific methodology needs to be followed for mulching and cover cropping under different soil, crop and climatic conditions to achieve improved soil health, sustainable crop production and mitigate the adverse impact of climate change.

This chapter examines the role of mulches and cover crops on soil health, environmental protection, crop growth and input-use efficiency. Part I of this topic deals with the types of mulches and cover crops and methods of their application.

Effect of mulching on soil health

Soil health can be defined as "the continued capacity of soil to function as a vital living system, within ecosystem and land use boundaries, to sustain biological productivity, maintain the quality of air and water environments, and promote plant, animal and human health" (Doran et al., 1996). Soil health or quality includes three groups of mutually interactive attributes, i.e., soil physical, chemical and biological quality, which must be restored to its optimum to sustain or even improve productivity in the long run.

Soil moisture regime

Mulching favorably influences the soil moisture regime by controlling evaporation from soil surface, improving infiltration and soil moisture retention and facilitating condensation of water at night due to temperature reversals.

Controlling evaporation from the soil surface

Mulching reduces evaporation from the soil surface by reducing the intensity of radiation and wind velocity. It retards evaporation mainly during the initial energy-limited stage of drying, but is less effective in controlling evaporation during the falling rate or supply-controlled stage. During this stage, the soil surface dries under the mulch and the vapor transfer of water to the atmosphere is inhibited more by the dry soil than the overlying vegetative mulch. Furthermore, the effectiveness of porous mulches, including surface cultivated soil mulch, decreases with time. Over long periods the cumulative evaporation losses from cultivated and no till soils may be similar even on soils that responds to the mulch application. When the loss of evaporation is decreased in the soil during the terminal phase of evaporation and water loss occurs only through movement in soil as vapor, the rates of evaporation are governed by the porosity and thickness of the dry layer (Acharya and Prihar, 1969). In addition to porosity and thickness of the dry layer, climatic conditions, especially wind velocity, also govern evaporation loss at this stage (Prihar et al., 1968; Acharya and Prihar, 1969). A more porous soil and lower wind velocity might lose less moisture through vapor transfer than a less porous soil and high wind velocity.

Higher rates of mulching retard the energy reaching the soil surface and hence limit evaporation losses at the constant rate stage (Bond and Willis, 1969). The retardation of initial evaporation can also enhance the process of internal drainage and thus can allow more water to migrate into the deeper parts of the profile, where it is less likely to be lost by evaporation and can be stored.

Mulching also affects the pattern of evaporation by offering resistance to water vapor flow from the soil surface to the atmosphere and by increasing the thickness of the relatively non-turbulent air zone above the soil, thus changing the boundary layer conditions of the soil-air interface. Relative magnitude of the reduction in evaporation for different mulch amounts is much greater under high evaporative demand. The cumulative reduction in evaporation due to mulching follows a quadratic relationship with time. The magnitude and time required to reach maximum reduction in evaporation depend on the method and rates of mulch application, soil type and magnitude of evaporative demand (Fig. 1) (Prihar et al., 1996). Orientation of the residue, i.e., flat or matted vs. standing affects the porosity and thickness of the layer and thus the rate of evaporation from the soil surface. With increasing amounts of standing residue higher wind speeds are needed to induce evaporation, and rates of water loss are reduced. Residue position also affects soil temperature (Table 1), which in turn affects the rate of evaporation through its influence on the vapor pressure of the soil water (Unger, 1990).

Water saving under mulching is prominent if rains are frequent. However, under extended dry periods mulches may keep the soil surface moist for longer and hence the first stage of evaporation is extended, but the net saving of water is negligible.

Improving infiltration

Mulching with organic materials serves as a barrier for runoff, which enhances water infiltration. Second, mulch intercepts rainwater and protects the soil. Furthermore, decomposition of organic mulches adds organic matter, improves the macro porosity and stability of soil and thereby improves water transmission properties (Lal, 1987), which enhance infiltration and recharge of the soil profile. Straw mulch application increases soil water storage and storage efficiency. The amount of water storage in the soil profile,

Fig. 1 Rate of cumulative evaporation reduction (CER) in two different soils under two wheat (*Triticum aestivum* L.) straw mulch application rates (3 t ha⁻¹ and 6 t ha⁻¹) at two evaporative demands (E₀). storage efficiency, total water use and water-use efficiencies of dryland crops increase with increased mulch rates (Table 2), and may outweigh the benefits of reduced evaporation in terms of water conservation (Unger, 1990).

Soil moisture retention

Mulching improves moisture retention properties of soil through its effect on pore-size distribution and soil structure. Higher rates of mulch application increase soil-water retention more at lower suctions (Lal, 1987) with the increase in macropores and inter-aggregate pores resulting from enhanced soil organic matter content and greater activity of soil fauna, e.g., earthworms and termites in mulched plots.

Water condensation at night

Stone and gravel mulches induce lateral movement of heat and vapor, which could in turn collect water under the stones due to condensation at night in amounts sufficient to serve as the sole water source for some species of desert plants.

Controlling runoff and soil erosion

Mulching invariably decreases soil erosion and often reduces runoff rates and volumes. Mulch cover protects the soil from raindrop impact and surface sealing, increases the infiltration of water and decreases run-off velocity through physical resistance to water flow. In general, water loss through runoff decreases exponentially with increasing mulch amounts (Table 3) (Erenstein, 2002). Runoff water is filtered through the mulch, which reduces sediment loads and erosion. Mulching also decreases sediment concentration in runoff water through the protective effect of crop residues against raindrops.

Ranaivoson et al. (2017) reported that soil erosion decreased markedly with increasing amounts of surface crop residues (Fig. 2). Residue amounts of 2–4 t dry matter ha⁻¹ reduced soil erosion by about 80% compared to bare soil. With 8 t dry matter ha⁻¹ of residues and above, there was virtually no more soil loss. It was observed that when around 60% of the soil was covered soil loss was reduced by an average of 80%. The boundary line showed that the maximum effects of surface residue amounts on soil erosion were reached with 2 t ha⁻¹ of residues (Fig. 2a). This corresponds to 80% soil cover or more (Fig. 2b). Residue cover dissipates raindrop energy and reduces the velocity of runoff flows by the interception of precipitation, thereby decreasing soil detachment (Gilley et al., 1986). It protects the physical structure of topsoil, improves aggregate stability and minimizes surface crusting (Jordán et al., 2010), which facilitates infiltration and hence reduces runoff and soil erosion.

Acharya et al. (1993), in a 5-year study with maize (*Zea mays* L.)–wheat cropping sequence on a silty clay loam under rainfed conditions, showed that under conservation tillage, involving the concept of agro-forestry, the minimum tillage with a mulch of robinia (*Robinia pseudocasia* L.) planted on either side of the terraces to generate mulching material and crop residues (1:1), the runoff losses were 7–19% of the total rainfall compared to 19–34% under conventional tillage. Therefore, more rainwater entered the soil profile under the former than the later treatment.

Table 3 Effects of rice (*Oryza sativa* L.) straw mulch rates on runoff and soil loss in Nigeria.

Mulch rate (Mg ha ⁻¹)	Run off (%)	Soil loss (Mg ha ⁻¹)	Marginal conservation effect (Mg soil) (Mg mulch) ⁻¹
0	75.4	9.6	–
2	43.4	2.3	3.7
3	15.2	0.5	1.8
6	5.4	0.1	0.13
12	0	0	0.017

Fig. 2 Effect of crop residue mulching on soil erosion control; Y_m = soil erosion under mulching and Y_b = soil erosion under bare soil. Source: Ranaivoson et al. (2017) *Agronomy for Sustainable Development* 37: 26.

The rate of soil loss decreases exponentially with the increase in percentage area covered by mulch. The mulch factor (MF) defined as the ratio of soil loss with mulch to that without mulch, is related to the percentage residue cover (RC) or mulch cover by the following expression (Morgan, 2005):

$$MF = e^{-a RC}, \quad (1)$$

where, a ranges between 0.03 and 0.07; generally a is set to 0.05. Eq. (1) is valid for rill erosion, whereas inter-rill erosion decreases linearly with mulch cover. For most soils, percentage mulch residue cover and slopes longer than 25 m mean the contribution of inter-rill erosion to total soil loss is quite small. Thus, Eq. (1) is generally used to compute MF. This mulch factor is multiplied by RC values to account for the effect of mulching in the universal soil loss equation (USLE). A minimum 50% soil cover is required to achieve soil loss reductions. Ideally, a mulch should cover 70–75% of the soil surface. The optimum mulch rate can be computed for a pre-selected set of conditions using the Manning equation for flow velocity and the relationship between Manning's n and the mulch rate is given below:

$$n = (r^{0.67} S^{0.5})/v, \quad (2)$$

where, r is the hydraulic radius, (m) S is the slope and v is the desired maximum flow velocity (m s^{-1}).

According to Foster et al. (1982), n_m , Manning's n as affected by a mulch cover, can be calculated as.

$$\left(n^{3/2} - n_s^{3/2} \right)^{2/3}, \quad (3)$$

where, n_s is Manning's n for a particular soil, s.

The mulch rate (M , kg m^{-2}) is related to the Manning's n for mulch (n_m) by the following relationship.

$$n_m = 0.071 M^{1.12} \quad \text{for inter-rill erosion} \quad (4)$$

$$n_m = 0.105 M^{0.84} \quad \text{for rill erosion} \quad (5)$$

Experimental evidence shows that an adequate quantity of crop residue mulch can mitigate the effect of the degree of slope in reducing soil loss.

Mulching is also effective in reducing wind erosion by reducing its velocity on the soil surface, provided that the mulch is not blown up by wind. Standing crop residues are more effective than flattened surface mulches in reducing wind erosion. The effectiveness of standing crop residues depends upon size and number of stalks per unit area.

Modifying the soil thermal regime

Mulches have a moderating influence on the soil thermal regime and the effect varies among soils, climates, mulch materials and their application rates. They increase soil temperature during cooler weather and decrease it during hot spells. In general, mulches have a damping effect on the amplitude of the diurnal fluctuations in soil temperature. Organic mulching enhances the soil temperature at night and in the early morning, but it decreases the daytime temperature compared to unmulched plots (Bhagat and Acharya, 1987).

Mulching is commonly practiced for some fruit crops like strawberries to keep the fruit clean by avoiding direct contact with soil and moderating the soil hydrological and thermal regimes for better productivity and quality of the fruit. Transparent polythene mulch produces the maximum soil temperature, whereas organic mulches like pine needles (*Pinus*) and grass (*Poaceae*) mulches lower it. Black polythene mulch, however, does not alter the maximum soil temperature appreciably (Fig. 3). The application of straw mulch can lower the maximum soil temperature due to interception of the incoming solar radiation, high reflectivity and low heat conductivity, the magnitude of which depends upon soil wetness, incidental radiation, rate of mulch application, and time of the year (Prihar, 1986). The decrease in maximum soil temperature by straw mulching during the early stage of growth of sugarcane (*Saccharum officinarum* L.) can significantly improve the yield.

Blanco-Canqui et al. (2006) observed that soil temperature decreased with the increase in rates of maize stover cover, except during winter (Fig. 4). The bare soil without stover consistently had the highest soil temperature for all stover rate treatments. The temperature from June to October decreased with the decrease in rate of stover removal (Blanco-Canqui and Lal, 2009). Stover removal at rates >25% strongly altered the soil temperature regime. On average, there was a drop of 5 °C when stover removal rate increased from 0 to 75% regardless of soil type. No significant differences in soil temperature were observed for stover removal rates of 75% and 100%. Lower soil temperatures in soils with residue retention are attributed to the fact that mulch cover significantly alters the radiation balance. Light colored stover cover has a high albedo and reflects incoming solar radiation at the soil surface (Chaudhary and Acharya, 1993; Horton et al., 1994).

Changing soil aeration

Crop residue mulches improve soil aeration by promoting free exchange of gases between soil and atmosphere. This is facilitated by increased soil structural stability, total porosity and macroporosity, decreased surface crusting, which all contribute to improved overall soil drainage. The rate of oxygen diffusion is higher under mulches. The gaseous composition of soil air under a mulch depends on the nature of its material (C:N ratio), its rate of decomposition, the soil moisture regime and climatic conditions. Plastic

mulch is practically impervious to carbon dioxide (CO_2), a gas that is of prime importance for photosynthesis. The CO_2 that accumulates under plastic escapes through the planting holes causing a 'chimney effect', which results in localized large CO_2 concentrations that accelerates crop growth.

Improving soil structure

Mulching improves soil structural properties directly by preventing raindrop impact and indirectly by promoting biological activity. Organic mulching improves the mean weight diameter of water stable aggregates, because of the addition of organic matter with decomposition of the mulch by soil microorganisms. The mean weight diameter of water stable aggregates increases with increased mulching rates (Table 4) (Lal, 1987).

In general, under mulched conditions, the bulk density of the soil is lower than without mulching. Bulk density decreases with increased mulch residue. This can be attributed to higher organic matter contents (Hati et al., 2006), improved aggregation and consequently increased total porosity, decreased compaction (Leroy et al., 2008) and increased root growth, earthworm activity and biopore formation (Bandyopadhyay et al., 2010). Chatterjee et al. (2016) reported a significant increase in the mean weight diameter, percentage of water stable aggregates, soil physical health indices like the 'S' index and least limiting water range (LLWR) from the application of wheat residue mulch in maize under a sandy loam soil.

Table 4 Effect of maize (*Zea mays* L.) straw mulch rate on pore size distribution of 0–5 cm layer of an Alfisol after 18 months of initiation of the experiment.

Mulch rate (Mg ha^{-1})	Porosity (%)			Mean weight diameter (mm)
	Macro ($>75 \mu\text{m}$)	Meso ($30\text{--}75 \mu\text{m}$)	Micro ($5\text{--}30 \mu\text{m}$)	
0	17.9	7.1	23.1	1.2
2	20.6	7.2	22.4	1.4
4	27.7	8.4	18.7	2.1
6	28.9	8.3	17.9	2.0

Improving the soil chemical environment

Organic mulches add organic matter and plant nutrients to soil with decomposition which increases carbon sequestration. The volatilization and leaching losses of nitrogen are reduced under mulched conditions. During mulch decomposition soil mineral nitrogen is immobilized by microbes. Cation exchange capacity and thus soil fertility are substantially influenced by increased organic matter contents in soils containing predominantly low activity clays. Furthermore, decomposition of organic mulches adds organic acids to the soil lowering the soil pH, which influences the bioavailability of many plant nutrients such iron, zinc and copper. Mulches also influence the availability of nutrients through their influence on physical and biological soil conditions described above.

Changing soil biological activity
